MEMORANDUM HUR-

Revised Standard Project Hurricane Criteria for the Atlantic and Gulf Coasts of the UNITED STATES

(DRAFT)

~~June 1972~~

MH December 1972

DEPARTMENT OF THE ARMY
OFFICE OF THE CHIEF OF ENGINEERS
WASHINGTON, D.C. 20314

IN REPLY REFER TO
DAEN-CWE-Y

31 July 1972

SUBJECT: Memorandum HUR 7-120, Revised Standard Project Hurricane Criteria for the Atlantic and Gulf Coasts of the United States

District Engineer, New Orleans

Subject memorandum has been prepared by the Hydrometeorological Branch, National Weather Service, in draft form and is being forwarded for interim use pending its final publication which will include data on the probable maximum hurricane. This report represents all the major changes in Standard Project Hurricane (SPH) criteria given in National Hurricane Research Project No. 33, which was distributed in November 1959. The purpose of the report is to incorporate all the various revisions, principally the changes in wind fields associated with well-developed hurricanes of recent years.

MEMORANDUM HUR 7-120

REVISED STANDARD PROJECT HURRICANE CRITERIA FOR THE ATLANTIC AND GULF COASTS OF THE UNITED STATES

Hydrometeorological Branch
Office of Hydrology
NOAA, National Weather Service
June 1972

I. Introduction

This memorandum covers revisions to Standard Project Hurricane (SPH) criteria given in National Hurricane Research Project Report No. 33 [1]. The need for these revisions was prompted by a comparison of the wind fields in well-developed hurricanes that occurred since 1956 with those used to develop the SPH in the original study. It is believed the wind fields or average radial storm winds of NHRP No. 33 should be stronger relative to the highest winds near the center of the storm. This is supported by the number of storms in recent years with winds that exceed those of NHRP No. 33. Figure 1 shows a comparison of the earlier radial wind profiles used in NHRP No. 33 with the profiles estimated in the more recent storms that bears out this contention. In this figure both velocity and distance are drawn on a relative basis, i.e., by ratios of actual wind to maximum wind and ratios of distance from the storm center to radius of maximum wind.

Memorandum HUR 7-84 [2] and several subsequent memoranda of that series provide revisions to NHRP No. 33 in zones B and C of the Gulf coast in order to better reflect the greater windspeeds of Hurricane Carla (1961) and others. Revisions of the present study are consistent with the revised values in zones B and C.

While the revision of the relative wind fields provide the main motivation for this work, other hurricane parameters were also updated, the most important being the Central Pressure Index (CPI). An important consideration in these revisions was to maintain consistency from zone to zone with a study giving meteorological characteristics of the probable maximum hurricane [3]. Criteria for the probable maximum hurricane (PMH) are the same meteorological parameters, some with the same values and similar developmental techniques, as those of the SPH criteria.

One reason why meteorological parameters, such as the CPI, need revision is that in the earlier storms the lowest pressure was seldom measured and therefore had to be estimated by indirect methods [4]. Exceptions were those storms where the center passed over a land station or a ship at sea. In recent storms much more reliable central pressures are often obtained through dropsondes from airplanes into the hurricane center.

The period of record for the revised SPH criteria includes all relevant storms in the 72-year period from 1900 through 1971.

Figure 2 shows revised values for maximum winds in the SPH along the Atlantic coast, with moderate forward speeds and mean radii of maximum winds, compared to the values previously published in NHRP No. 33. The increased winds up to about 35°N latitude are mainly due to lower CPI values in the revised analyses. The slightly lower winds farther north are due mainly to the adoption of a peripheral pressure that varies with latitude.

The present study is meant to be an interim report, giving the major changes in SPH criteria from that in NHRP No. 33. Many references are

made to that report. The planned publication of revised SPH criteria will contain the necessary information so that these references need not be made.

II. Interpretation of the SPH

The SPH is a hypothetical hurricane that is intended to represent the most severe combination of hurricane parameters that is "reasonably characteristic" of a specified geographic region, excluding extremely rare combinations. The SPH is intended as a practicable expression of the maximum ~~chance~~ DEGREE of protection that should be sought as a general rule in the planning and design of coastal structures for communities where protection of human life and destruction of property is involved. The height of the storm-generated surge is the critical factor. This is mainly dependent on the speed and direction of winds as a hurricane nears and enters the coast. Thus, the important product of the study is the hurricane wind field.

There have been numerous inquiries indicating there are some misunderstandings concerning what the SPH criteria represent. NHRP No. 33 and the present revision show frequency analyses of the CPI for large zones along the gulf and Atlantic coasts. The SPH uses the arbitrary 100-year return period of the CPI as a standard for comparison and consistency from zone to zone. However, use of 100-year return-period CPI values does not imply that the SPH has a 100-year return period for any place in a given zone, since other meteorological parameters are also important. Hence, the standard project hurricane has no frequency assigned to it. The angle of storm approach to the coastline, the rate of travel, and the radius of maximum wind are important meteorological considerations for determining the hurricane surge.

Although a CPI with a 100-year return period may be read from figures in this report for any point along the coast, it does not mean the value is expected to occur once in 100 years at that point. Because of the manner

in which the statistics of the CPI were developed (see pp. 3 and 4 in NHRP No. 33) the 100-year CPI at any point on the Atlantic coast, say x, must be interpreted as the CPI value which may be expected to occur once in 100 years, on the average, at some point in a 300 n. mi. zone centered at x. The smooth 100-year line which interpolates the CPI value from the mid-point of one zone to another is a convenience which insures a smooth regional progression of the CPI values.

Wind fields determined from NHRP No. 33 and this revision, represent 10-minute average speeds, standardized to a height of 30 feet above the surface. The 10-minute average was adopted as a standard sustained wind. Storm surges cannot be generated from wind gusts. The 30-ft height above the surface is used to standardize observations from instruments at differing heights.

III. SPH parameters

The independent parameters used to develop the SPH criteria are:

1. Central Pressure Index (CPI). This is the lowest pressure at the storm center. It is an independent variable for determination of the maximum gradient windspeed (V_{gx}).

2. Peripheral Pressure (p_n). This is the sea-level pressure at the outer limits of the hurricane wind circulation. It should not be confused with the assymptotic pressure discussed in [3]. Revised maximum wind (V_x) values for this report (see Part IV, F) where p_n depends on latitude are shown in figure 2.

3. Radius of maximum wind (R). This is the radial distance from the hurricane center to the location of highest winds which usually occurs just outward the hurricane eye-wall cloud.

4. Forward speed (T). This is the rate of translation of the hurricane center from one geographical point to another.

IV. Revisions to NHRP Report No. 33

A. Added storm data

Table A lists hurricanes with central pressures of less than 29.00 inches within each coastal zone for the 72-year period of record (1900-1971). There are 32 more storms than shown for a similar list in NHRP No. 33.

Table B lists all tropical storms which reached hurricane intensity at some time and moved through one or more of the zones during the 72-year period of record (1900-1971). There is an increase of 50 in the number of storms over those in NHRP No. 33.

B. Central Pressure Index (CPI) frequency analyses

New frequency analyses, figures 3-9, were made for each zone using central pressures (p_o) from table A. Changes in zone B were dictated primarily by Hurricane Camille (1969).

C. Coastal profile of CPI

The variation of CPI along the coast was obtained by fitting smooth curves to the frequency analyses of the CPI values plotted at the coastal center of each zone. Analysis of the discrete 100-year return-period CPI values resulted in smooth profiles along the Atlantic coast, figure 10, and Gulf coast, figure 11, and provides the necessary continuity and consistency between the Atlantic and Gulf coasts.

D. Nomogram for wind field profiles

The generalized SPH wind field is paracentric. However, since it is symmetrical, a radial wind profile taken along the line of maximum wind (line M) may be used to reconstruct the entire wind field. This is done by rotating the profile about the storm center, adjusting the windspeed according to a simple cosine function.

A wind profile nomogram, figure 12, was developed from hurricane wind patterns observed along the Atlantic and Gulf coasts through 1971. From the nomogram the radial wind profile for a given radius of maximum wind is defined by relative wind values read from isolines of radial distance (r in n. mi.) from the storm center. The relative wind (V/V_x) is the ratio of the wind (V) at a radial distance (r) to the maximum wind (V_x) along that radius. Profiles are defined for all radii of maximum wind from 4 to 50 n. mi. This covers the SPH range from small (RS) to large (RL) radius.

Relative wind (V/V_x) profiles of some storms exceed those of the nomogram (see fig. 1). The percent of storms undercut is uncertain, but it is probably in the range of 10-15 percent. For instance in the period 1957 through 1971, 4 or 5 out of 32 hurricanes in the Gulf and Atlantic coastal areas had some portion of their relative wind profile undercut. The storms that were partially undercut are: Carla (1961); Donna (1960); Ione (1955); Hazel (1954); Gracie (1959); and Camille (1969). This, however, does not mean that the actual SPH winds undercut all of these storms since the maximum wind (V_x) must also be considered.

Profiles from the nomogram, figure 12, provide higher windspeeds relative to the maximum wind (V_x) than did NHRP No. 33 over the entire wind field in all zones. This is shown in figure 13, for zone C where the average increase along the profile is about 10 percent. The figure also shows profiles used in two earlier SPH wind field revisions [2, 5]. The increase over NHRP No. 33 for other zones ranges to about 20 percent for mean (RM) and large (RL) radii of maximum winds.

E. Maximum gradient windspeed (V_{gx})

The maximum gradient windspeed equation

$$V_{gx} = K\sqrt{p_n - p_o} - R\,(0.575f) \qquad (1)$$

from [4], provides a means for computing the maximum windspeed in a SPH whose other parameters are known. V_{gx} is in mph when P_n and p_o are in inches, R is in n. mi. and f is in hr^{-1}. The coefficient (K) varies with latitude [3] in the revised SPH criteria as opposed to a constant value of 73.0 used in NHRP No. 33. The peripheral pressure (p_n) also varies with latitude. Figure 14 shows a plot of p_n versus latitude in storms and the adopted curve.

The central pressure (p_o), the radius of maximum wind (R), and storm speed (T) are given in table 1. The values of V_{gx} for mean (RM) and large (RL) radius of maximum wind were computed and also appear in table 1, after conversion to knots.

F. Maximum windspeed (V_x)

The maximum windspeed, in knots, adjusted to 30 feet above the water surface is defined by the equation:

$$V_x = 0.865\ V_{gx} + 0.5T \qquad (2)$$

0.885 USED FOR PMH (7-97)
ZONE B

where the gradient windspeed, V_{gx}, from equation (1) is in knots and the forward speed, T, is in knots. V_x was evaluated at 48 discrete geographical locations on the Atlantic and Gulf coasts using the two values of V_{gx} (for RM and RL) for slow (ST), moderate (MT), and fast (HT) forward speeds. These values are listed in table 1. The same overwater friction coefficient, 0.865, for reducing the gradient wind to 30 feet above the surface, was used in all zones.

G. Wind fields

Construction of isovel patterns involves rotation of the radial profile of windspeed about the hurricane center. If this is done by hand computation techniques, it is necessary to first sketch the wind profile along the radius of maximum wind, using figure 12. Under normal circumstances this radius, or line of maximum winds, extends to the right of the direction of motion vector of the storm, making an angle of 115° with the direction vector. To get the windspeed, V_{xp}, at any point x, a distance r from the center of the SPH, and that does not lie on line M, the expression

$$V_{xp} = V_x - \frac{T}{2}(1-\cos\theta) \qquad (3)$$

is used. V_x is the windspeed along the profile on M at a distance r from the center and θ is the angle between line M and radius vector through x.

Although an angle of 115° between line M and the direction of storm motion is preferred, this angle may be any value from 15° to 165°. This agrees with the limits of rotation given in NHRP No. 33.

The wind direction is defined as the angle of incurvature over the wind field. The angle of incurvature is the angle between the wind direction and a tangent to a circle centered over the storm, and is considered to be positive when the wind has a component directed toward the storm center. The angle of incurvature criteria, the same as that shown in NHRP No. 33, is as follows.

Radius	Angle of incurvature
1. Center out to region of maximum winds (R)	0°-10°
2. R out to 1.2 R	10°-25°
3. 1.2 R and outward	25°

Radial wind profiles for each zone from this study are compared with those in NHRP No. 33, in figures 15 through 21. The profile for zone C, figure 21, was used to construct a sample wind field, figure 22. This is for mile 360 with a moderate forward speed and mean radius.

H. Radius of maximum winds (R) and forward speed (T)

Some of the values of the CPI (p_o) were revised, and since R is somewhat dependent on p_o (see figure 7 and 17, NHRP No. 33) the values of the three categories of R (small, mean, and large) were accordingly revised. The new values in table 1 are only slightly different from those in table 1 of NHRP No. 33.

The values of the three categories of the forward speed (slow, moderate, and fast), read from figures 9 and 20, NHRP No. 33, resulted in slight differences from those originally published in table 1.

I. Frictional adjustment for windspeeds over land

In NHRP No. 33, a constant factor of 0.70 was used for reducing over-water winds to over-land. For the present revision, we recommend a variation in this reduction factor with the windspeed. The basis for this is shown in figure 30 of HMR #32 [4]. For windspeeds less than 10 knots, use 0.40, for speeds greater than 73 knots use 0.78. Interpolate linearly for intermediate speeds. These reduction factors for any over-water speed represent lower limiting values for the over-land windspeed at a point which is at least 10 miles inland along a trajectory starting at the coast. In other words, the reduction should be accomplished in about 10 miles over land. The speed-up when the trajectory leaves land to go back over water also occurs in about 10 miles.

V. Other SPH criteria, not revised

Other criteria for the SPH, such as adjustment for filling over land, and adjustment of windspeeds near shore, have not undergone revision.

VI. Isovel wind field construction

The procedure for constructing a revised SPH wind field is illustrated by the following example for a location along the Atlantic coast at 25.5°N. latitude. This example uses a mean radius of maximum wind (RM) and a moderate forward speed (MT).

1. From table 1, mean radius of maximum wind, (RM), for the location is 8 n. mi., maximum windspeed (V_x) is 109 knots, and moderate forward speed (MT) is 10 knots.

2. Using figure 12, read off relative windspeeds (V/V_x) at various distances from the center for RM of 8 n. mi. For this example, the following table gives the V/V_x and the actual wind, V, at the given distances.

Distance from center (n. mi.)	V/V_x	V (kts)
8	1.000	109
9	.995	108
12	.970	106
16	.916	100
20	.823	90
30	.698	76
40	.619	67
50	.559	61
60	.506	55
80	.431	47
100	.368	40
120	.317	35
150	.244	27
200	.158	17

3. For the values of V inside RM, read off relative distances from the center and relative windspeeds from figure 23. Construct table, as in step 2.

Relative distance from center (r/R)	Relative speed (V/V_x)	$V = V/V_x$ x 109 (knots)	r = r/R x 8 (n. mi.)
.2	.025	3	1.6
.4	.117	13	3.2
.5	.227	25	4.0
.6	.450	49	4.8
.7	.735	80	5.6
.75	.835	91	6.0
.8	.900	98	6.4
.9	.970	106	7.2

4. Plot the values of steps 2 and 3, (V versus distance from center, r,) on graph paper, as in figures 24[1], upper right, and upper left. This gives the windspeed values for any point along the line of maximum winds.

5. On a large sheet (2'x2'), lay off a line (M), scaled with distance from a point designated as the center of the SPH. On this line, plot winds computed in steps 2 and 3 or interpolated from step 4. (See figure 24.)

6. To compute the windspeed V_{xp}, at any point x in the SPH wind field that does not lie on line M, use the following equation:

$$V_{xp} = V\text{-}T/2\ (1\text{-}\cos\theta),$$

where V is the windspeed along line M at the distance r from the center.

To show, in general, how the equation is used consider the point, x, 50 n. mi. from the storm center making an angle θ of 60° with line M.

[1]The plot, figure 24, should be on a reasonably large graph paper in order to obtain deatils on winds within RM. We suggest a sheet about 2½2'.

a. On figure 24 read V, along line M, of 61 knots at a distance of 50 n. mi. from the center.

b. Substituting in the equation gives

$$V_{xp} = 61 - \frac{10}{2}(1-.5) = 58.5 \text{ knots}$$

7. To determine a particular isovel, say for 40 knots, the following is suggested.

a. Mark the 40-knot point on line M, using figure 24, upper right, to get distance from the center.

b. Using the nomogram, figure 25, sketch in selected radial lines that indicate factors applied to forward speed (T) to find the 40-knot value at other points. These are tick marks .1, .2, etc., on figure 24, lower portion. Note that the 1.0 mark is diametrically opposite to line M.

c. To get the distance of the 40-knot value from the center along the radial tick mark 0.4, multiply 10 (the value of T) by 0.4 to get 4. Add 4 to 40 to get 44.

d. From upper right profile of figure 24, find the distance from center (along M), of the 44 knots and plot along line marked 0.4. This gives the location of the 40-knot wind on radial 0.4. Make similar computations for other radials to provide a smooth isovel around full circle of the pattern. Since the wind field is symmetrical about line M, half the pattern may be folded over to obtain the complete wind field.

e. For determining other isovels outside of R, follow the same procedure.

f. For isovels inside of R, use the same procedure, utilizing the wind profile in the upper left corner of figure 24.

A little experimenting will make the following evident. All isovels that have values larger than the differences between the maximum wind and the forward speed of the storm will be crescent or kidney-shaped. For the particular example above, where V_x = 109 and T = 10, all isovels with values between 99 and 109 are crescent-shaped. See example of the 100-knot isovel in figure 24. All other isovels are more or less circular.

Alternate to detailed approach. Without sacrificing much accuracy, all nearly circular isovels may be drawn as true circles, provided the forward speed, T, is relatively low, say, 12 knots or less. To do this for the 40-knot isovel as an example, perform step 7a above. To find the 40-knot point on the extension of M on the opposite side of the center use figure 24 again and find the distance from center to the 50 knot (40 + T = 50) value. Find the midpoint, on line M of the two points above, and using this as a center, draw a circle through the two points. This is the 40-knot isovel. Other isovels are determined in a similar manner.

CPI = central pressure index, estimated minimum pressure
RS = representative small radius to region of maximum winds
RM = representative mean radius to region of maximum winds
RL = representative large radius to region of maximum winds
ST = representative slow speed of translation of hurricane center
MT = representative moderate speed of translation of hurricane center
HT = representative high speed of translation of hurricane center
T = speed of translation of hurricane center
V_{gx} = maximum theoretical gradient wind computed for each CPI with P_n=29.92

V_x = estimated maximum 30-ft wind speed computed from V_x=0.865 V_{gx} + 0.5T

CUMULATIVE FREQUENCIES OF HURRICANE CENTRAL PRESSURES (1900-1971) ZONE 4

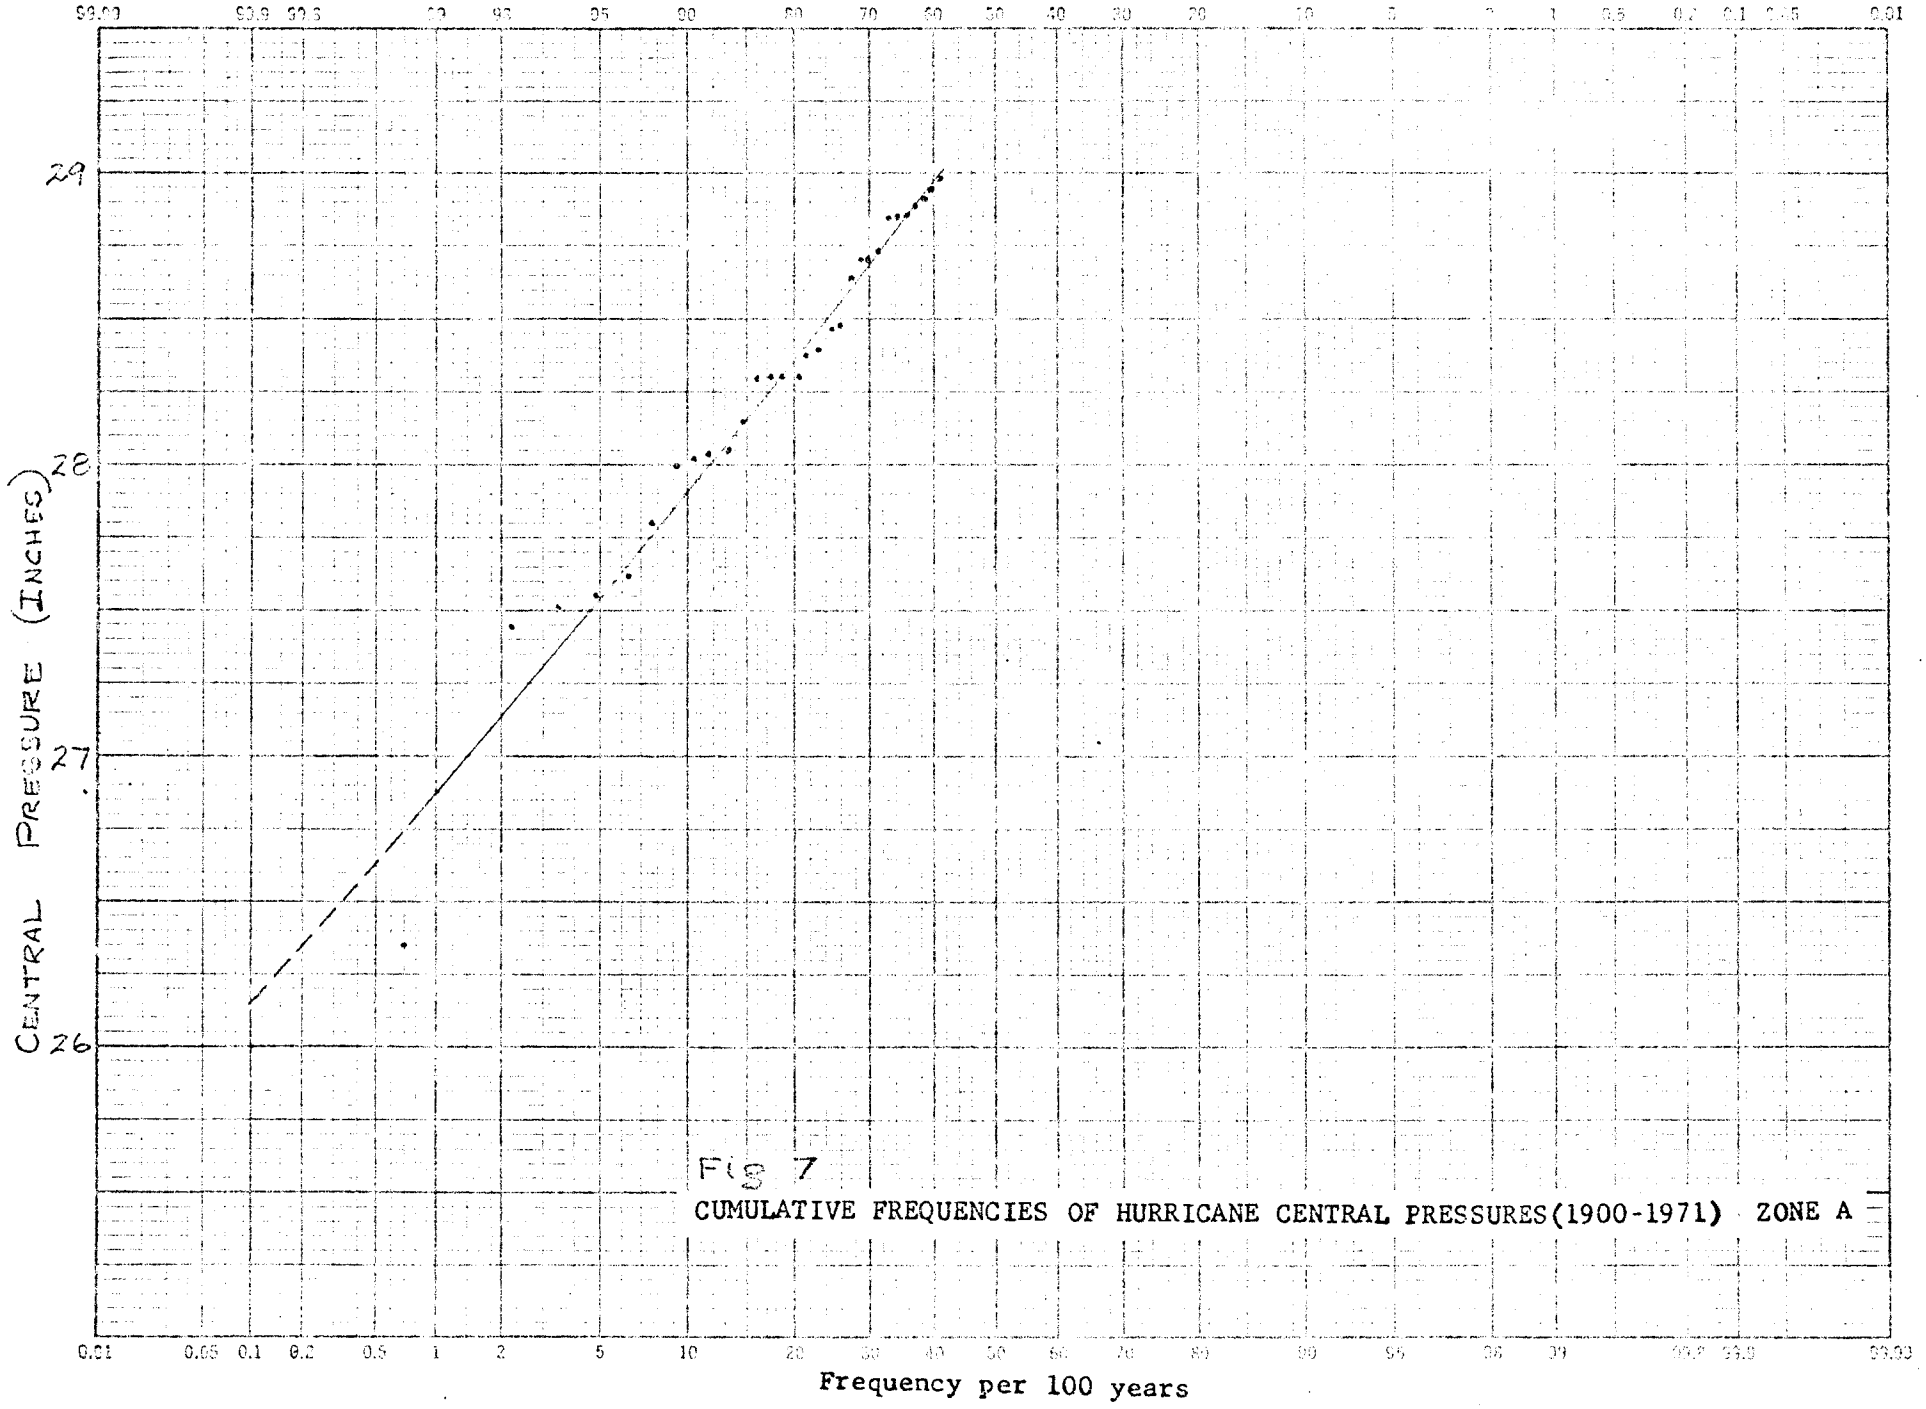

FIG 7

CUMULATIVE FREQUENCIES OF HURRICANE CENTRAL PRESSURES (1900-1971) ZONE A

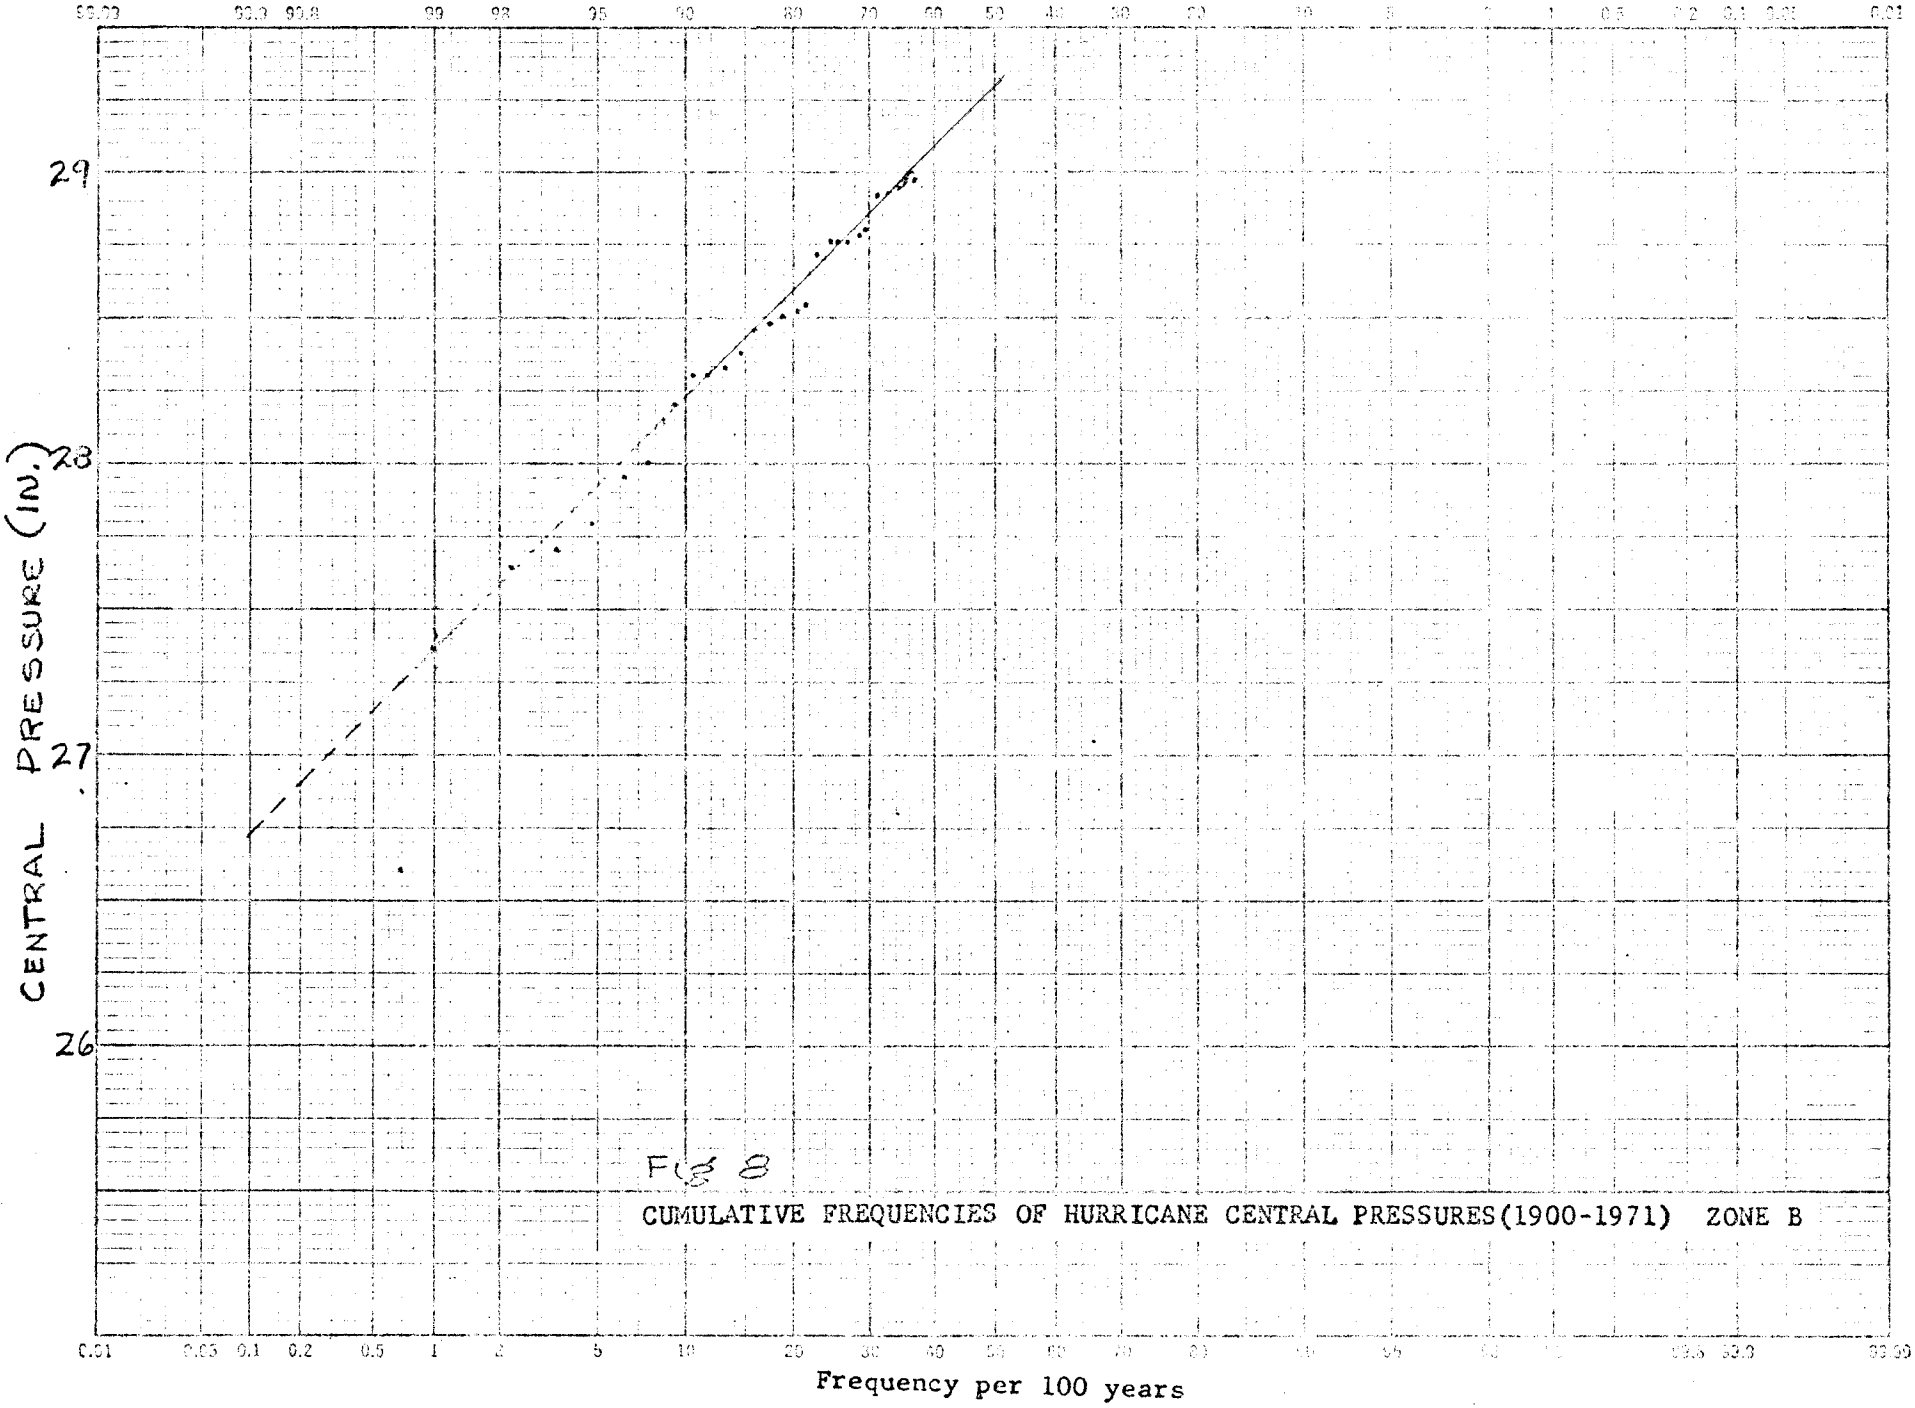

Fig 8

CUMULATIVE FREQUENCIES OF HURRICANE CENTRAL PRESSURES (1900-1971) ZONE B

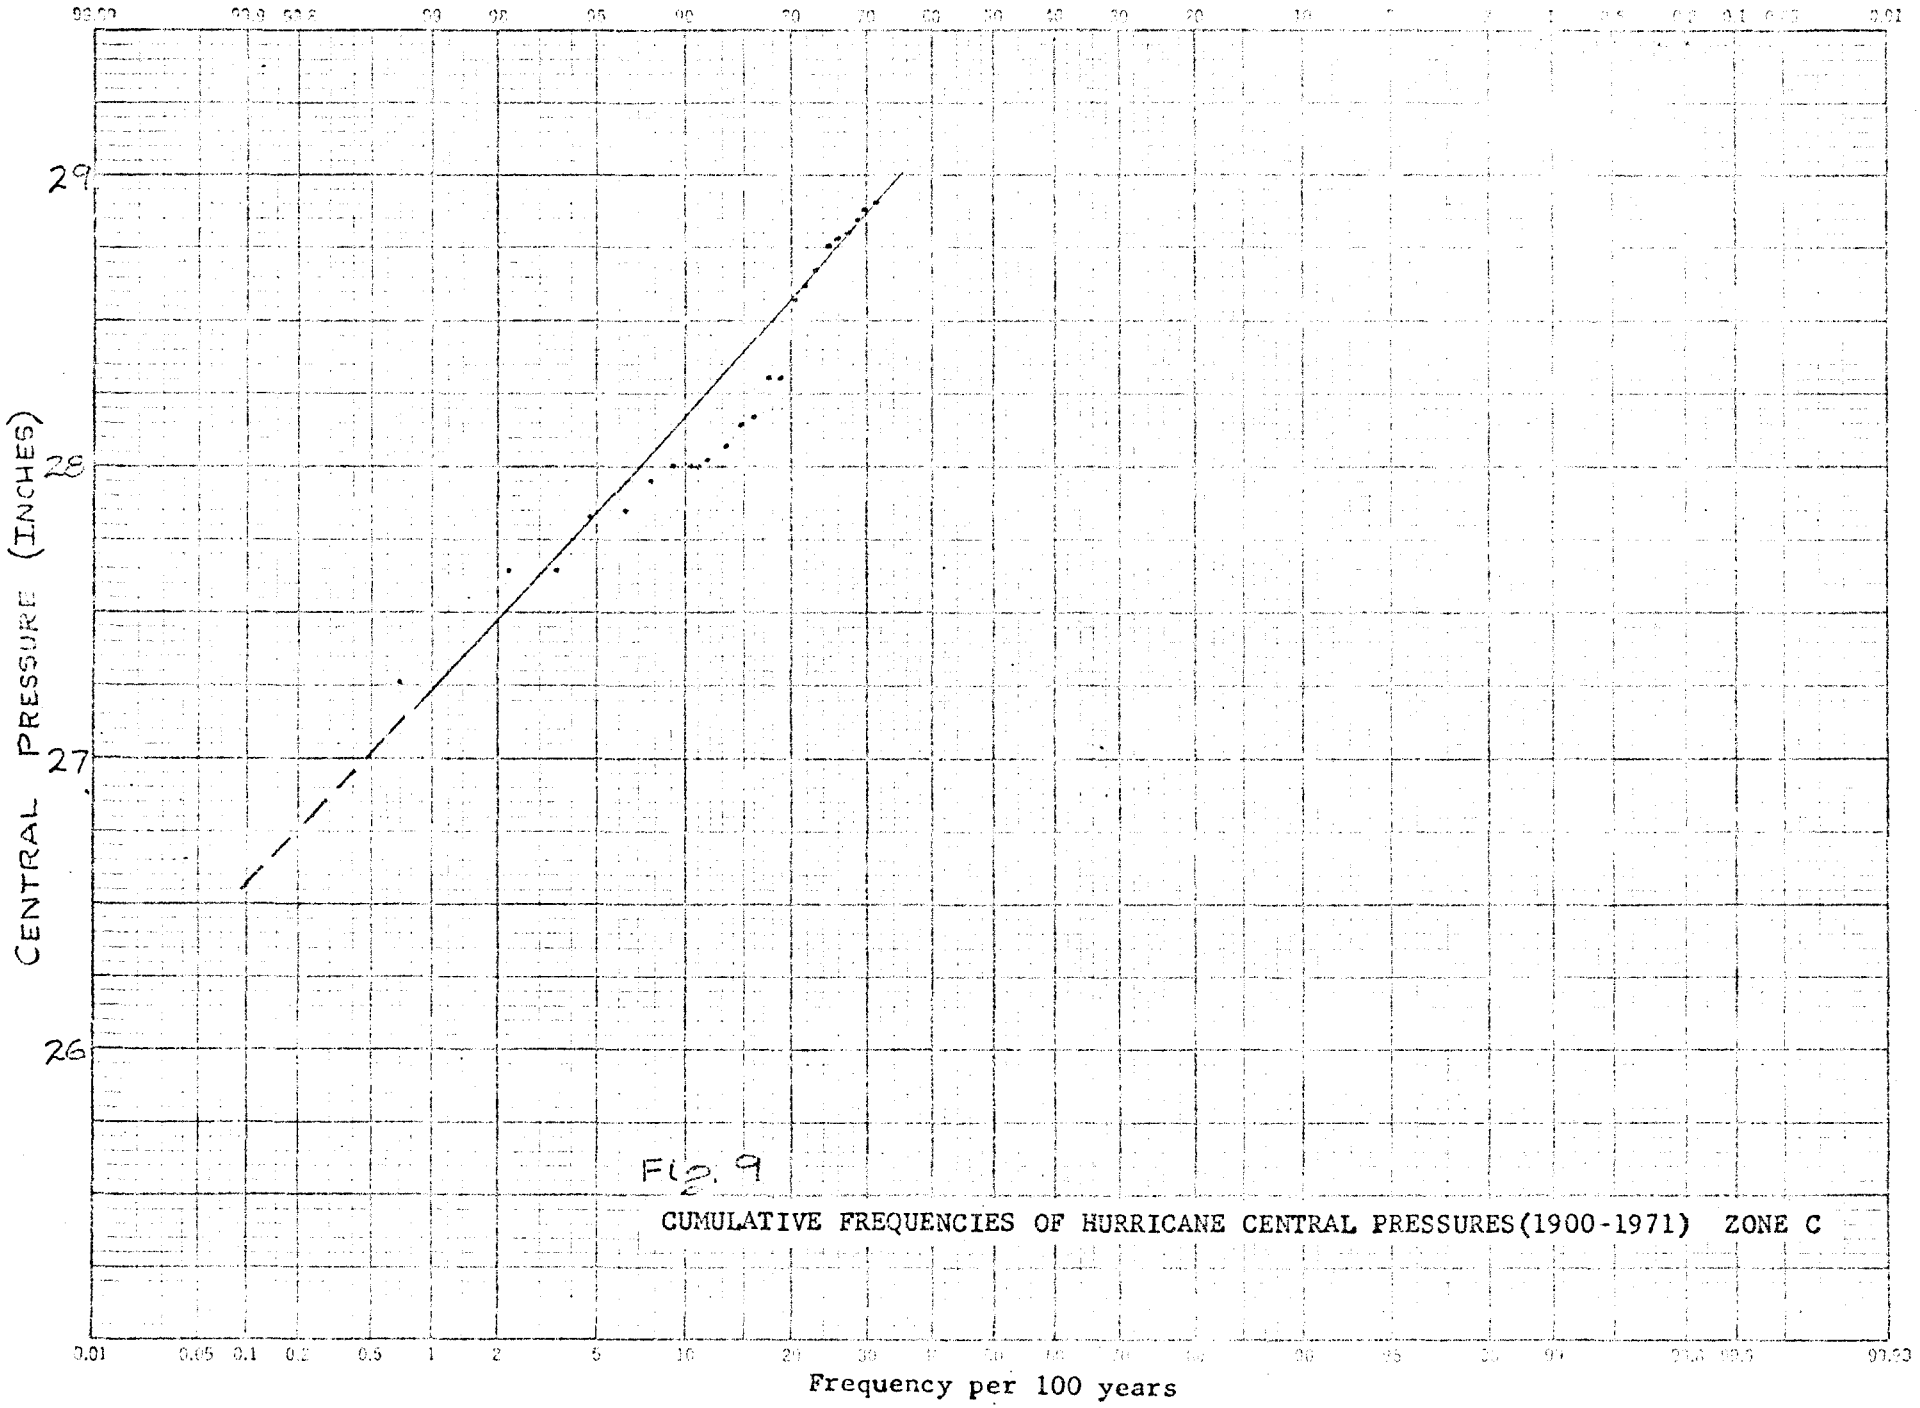

Fig. 9

CUMULATIVE FREQUENCIES OF HURRICANE CENTRAL PRESSURES (1900-1971) ZONE C

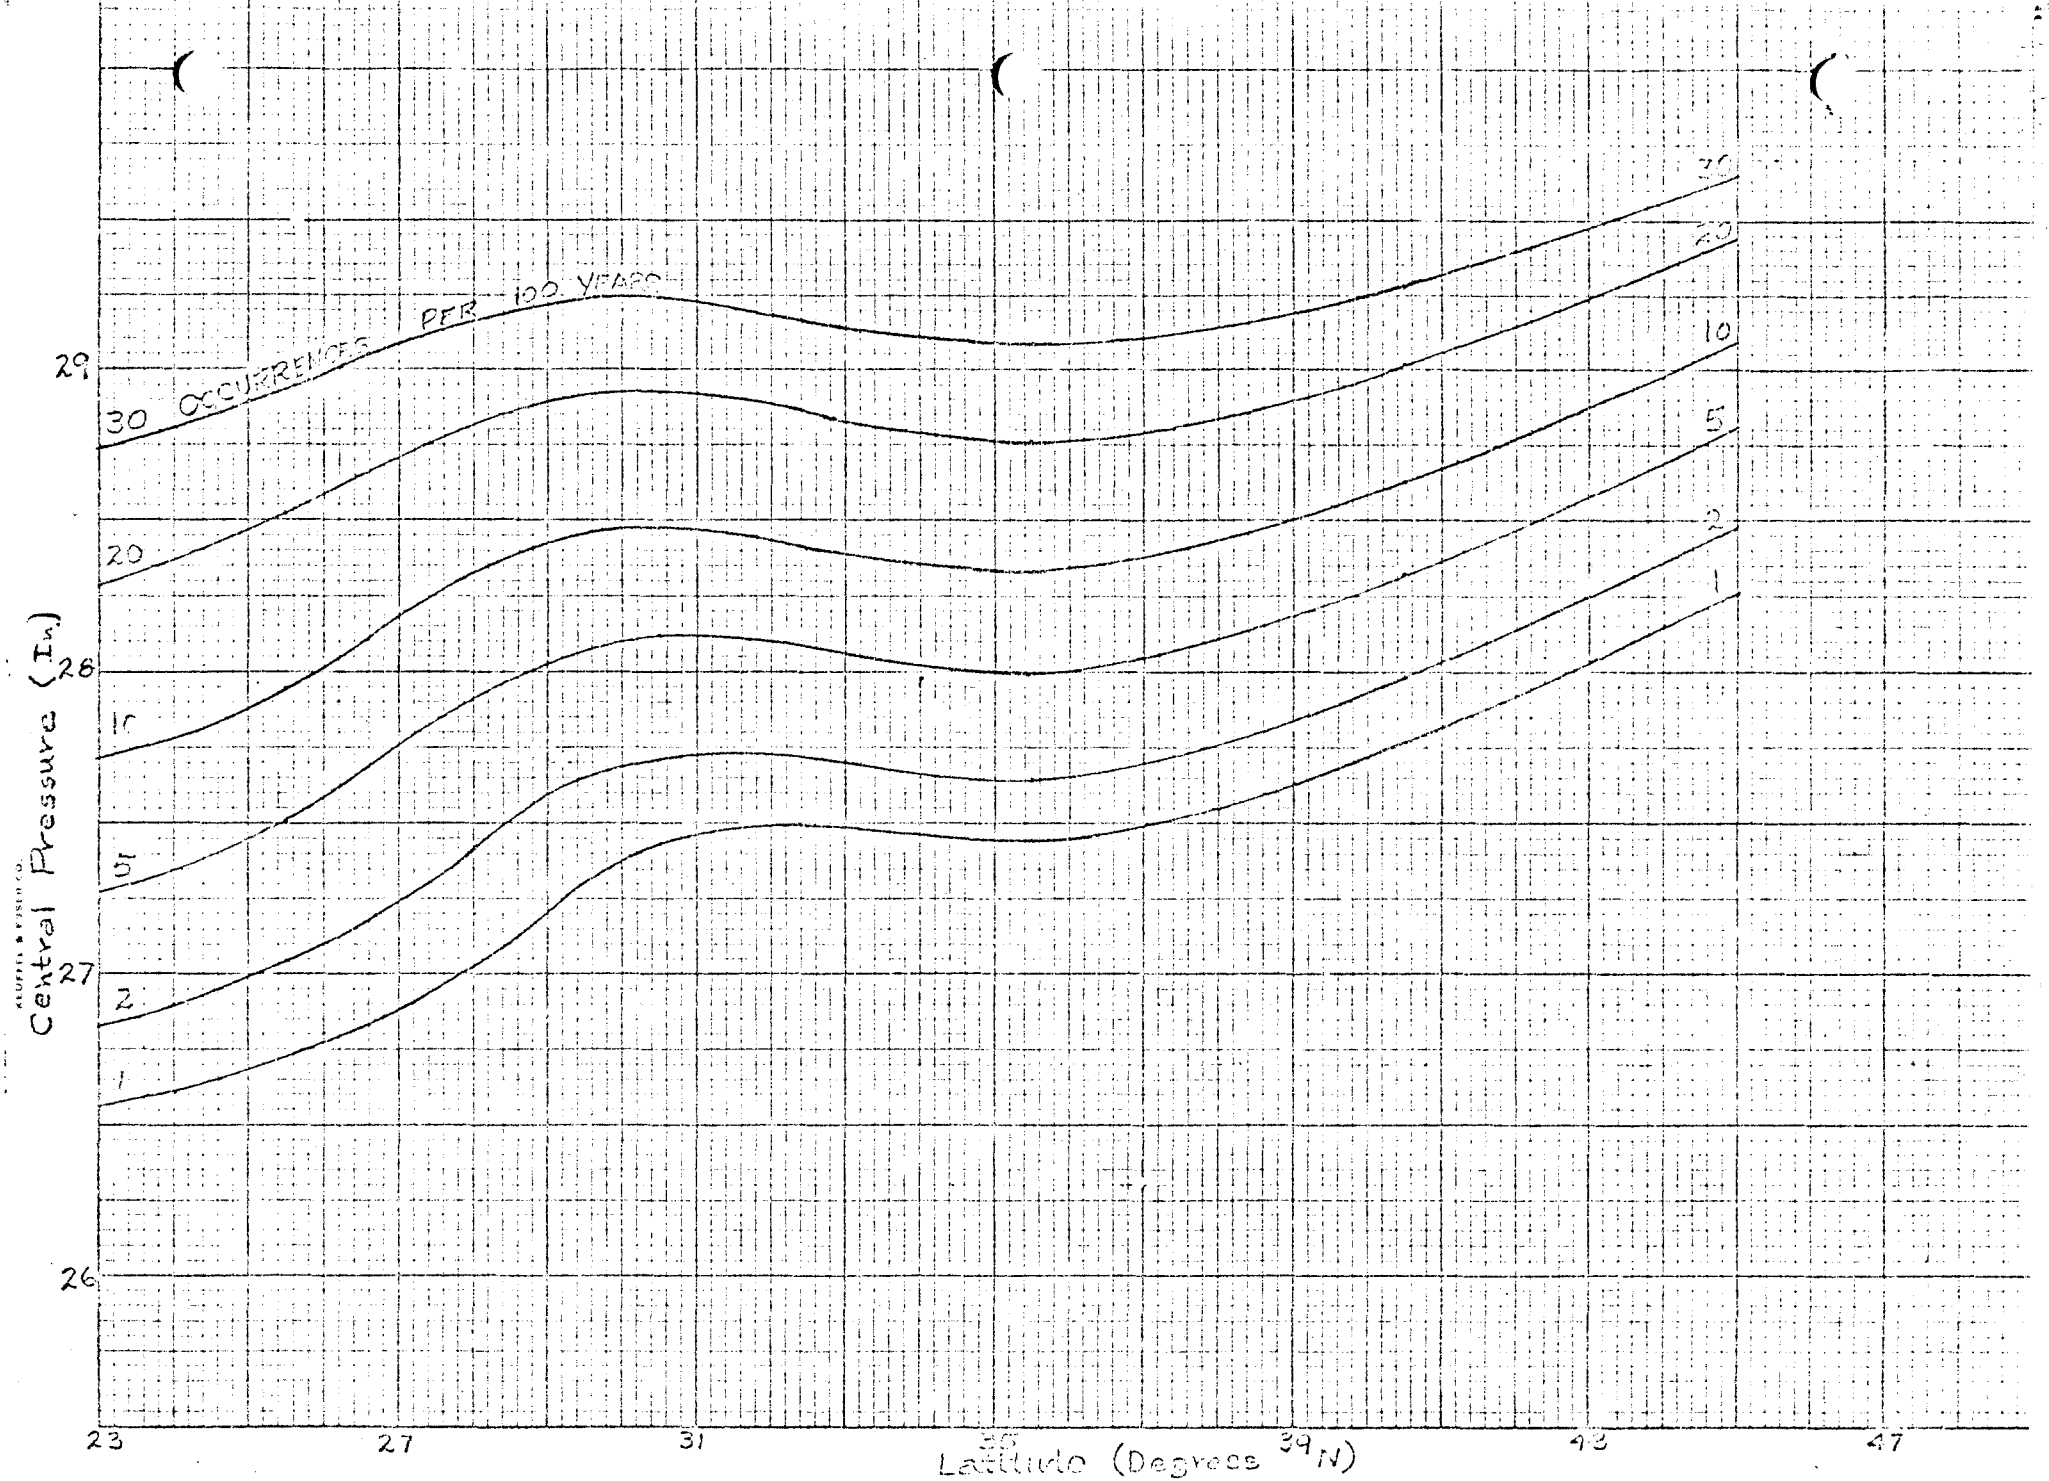

Fig. 10. LATITUDINAL VARIATION OF AVERAGE FREQUENCY PER 100 YEARS OF CPI, ATLANTIC COAST ZONES

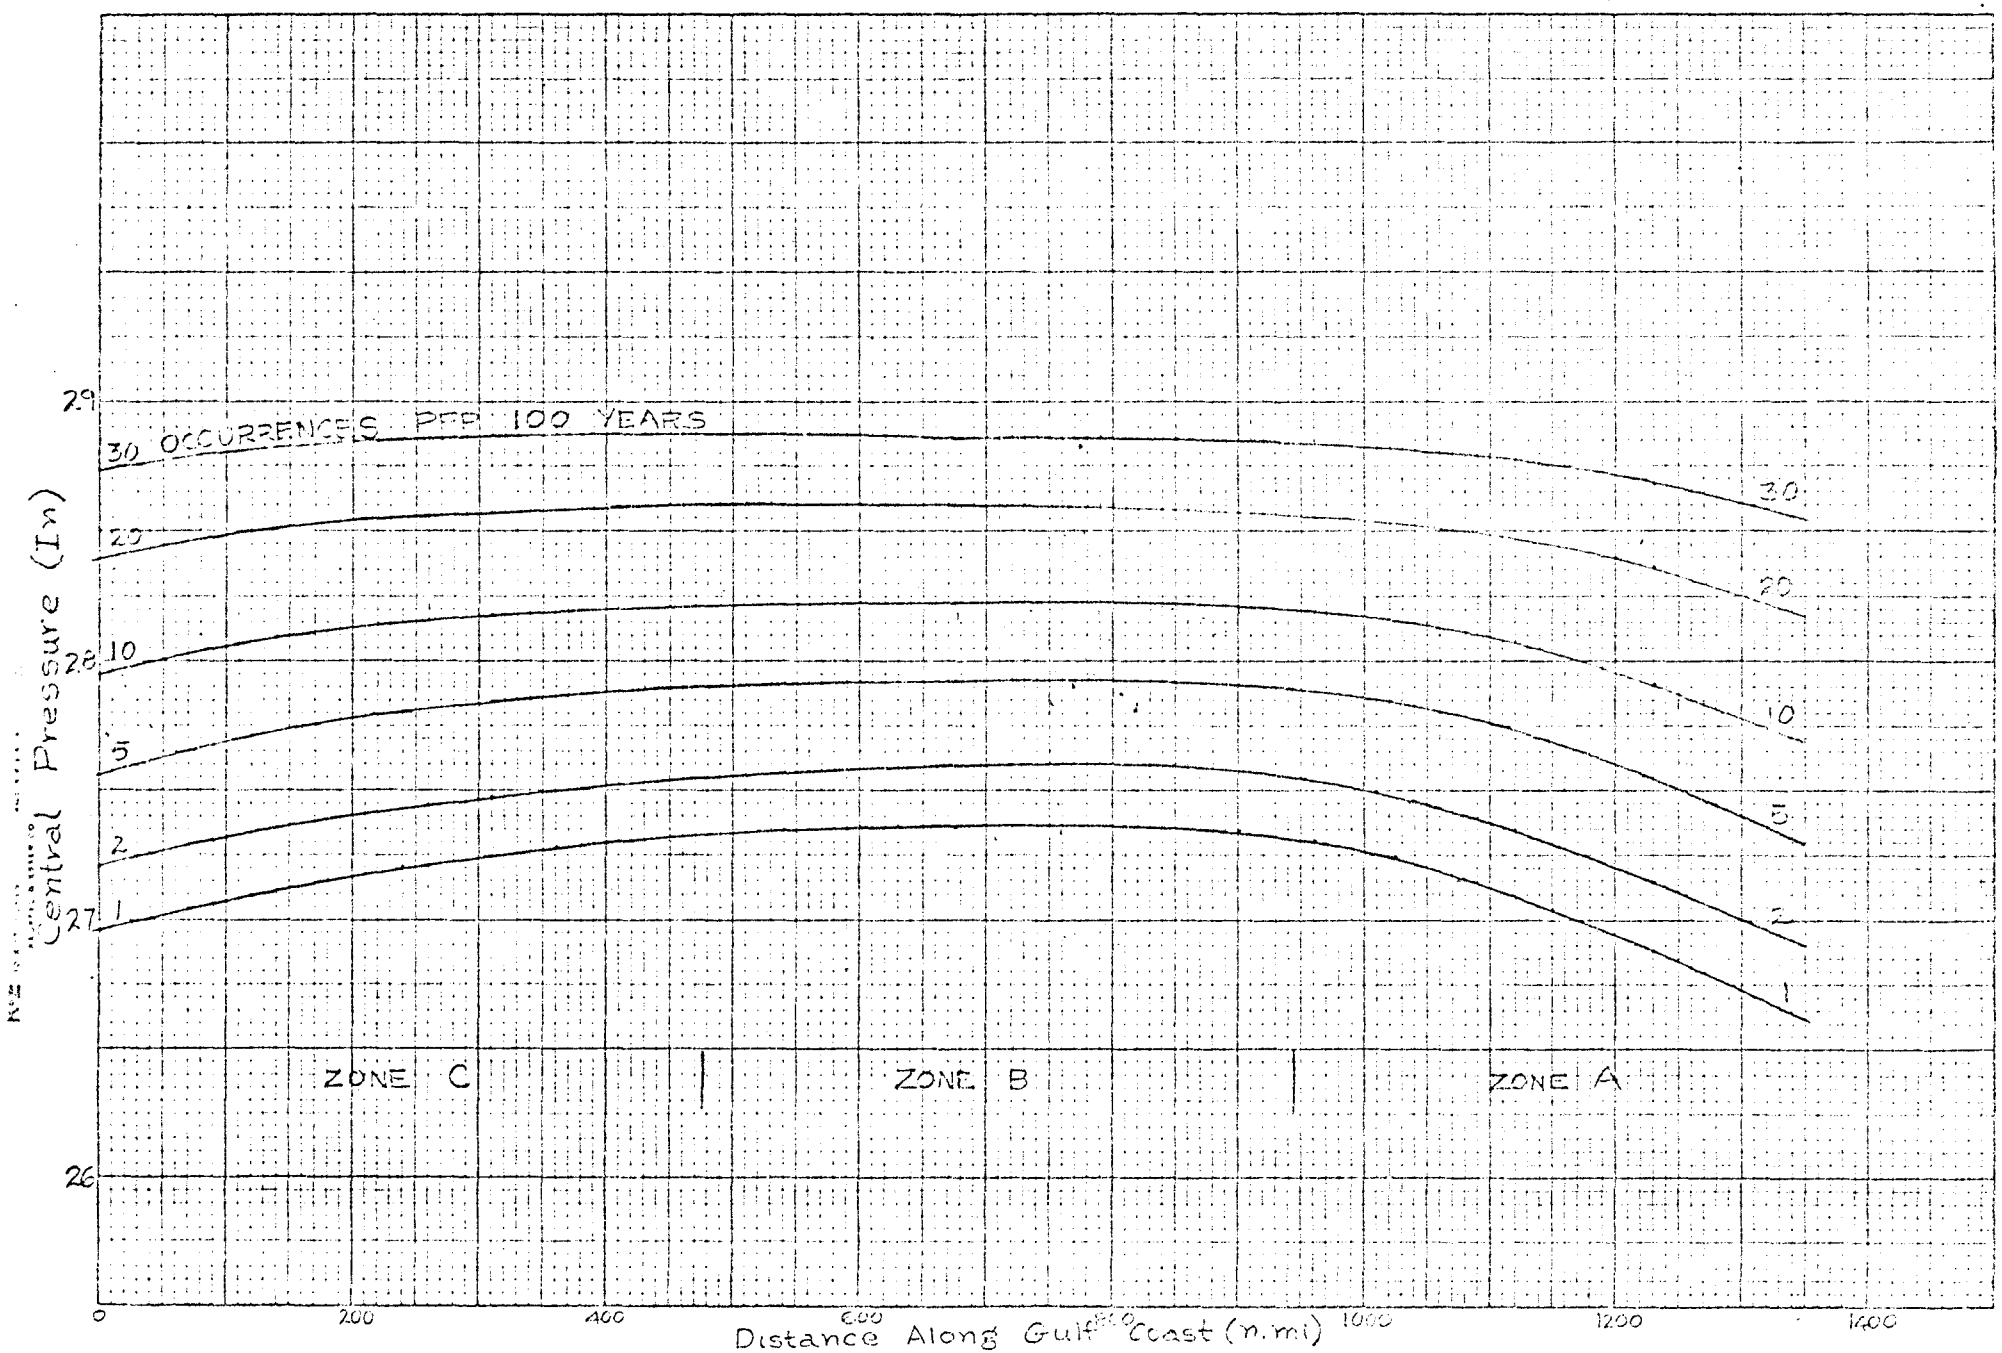

Fig. 11. GEOGRAPHICAL VARIATION OF AVERAGE FREQUENCY PER 100 YEARS OF CPI, GULF COAST ZONES

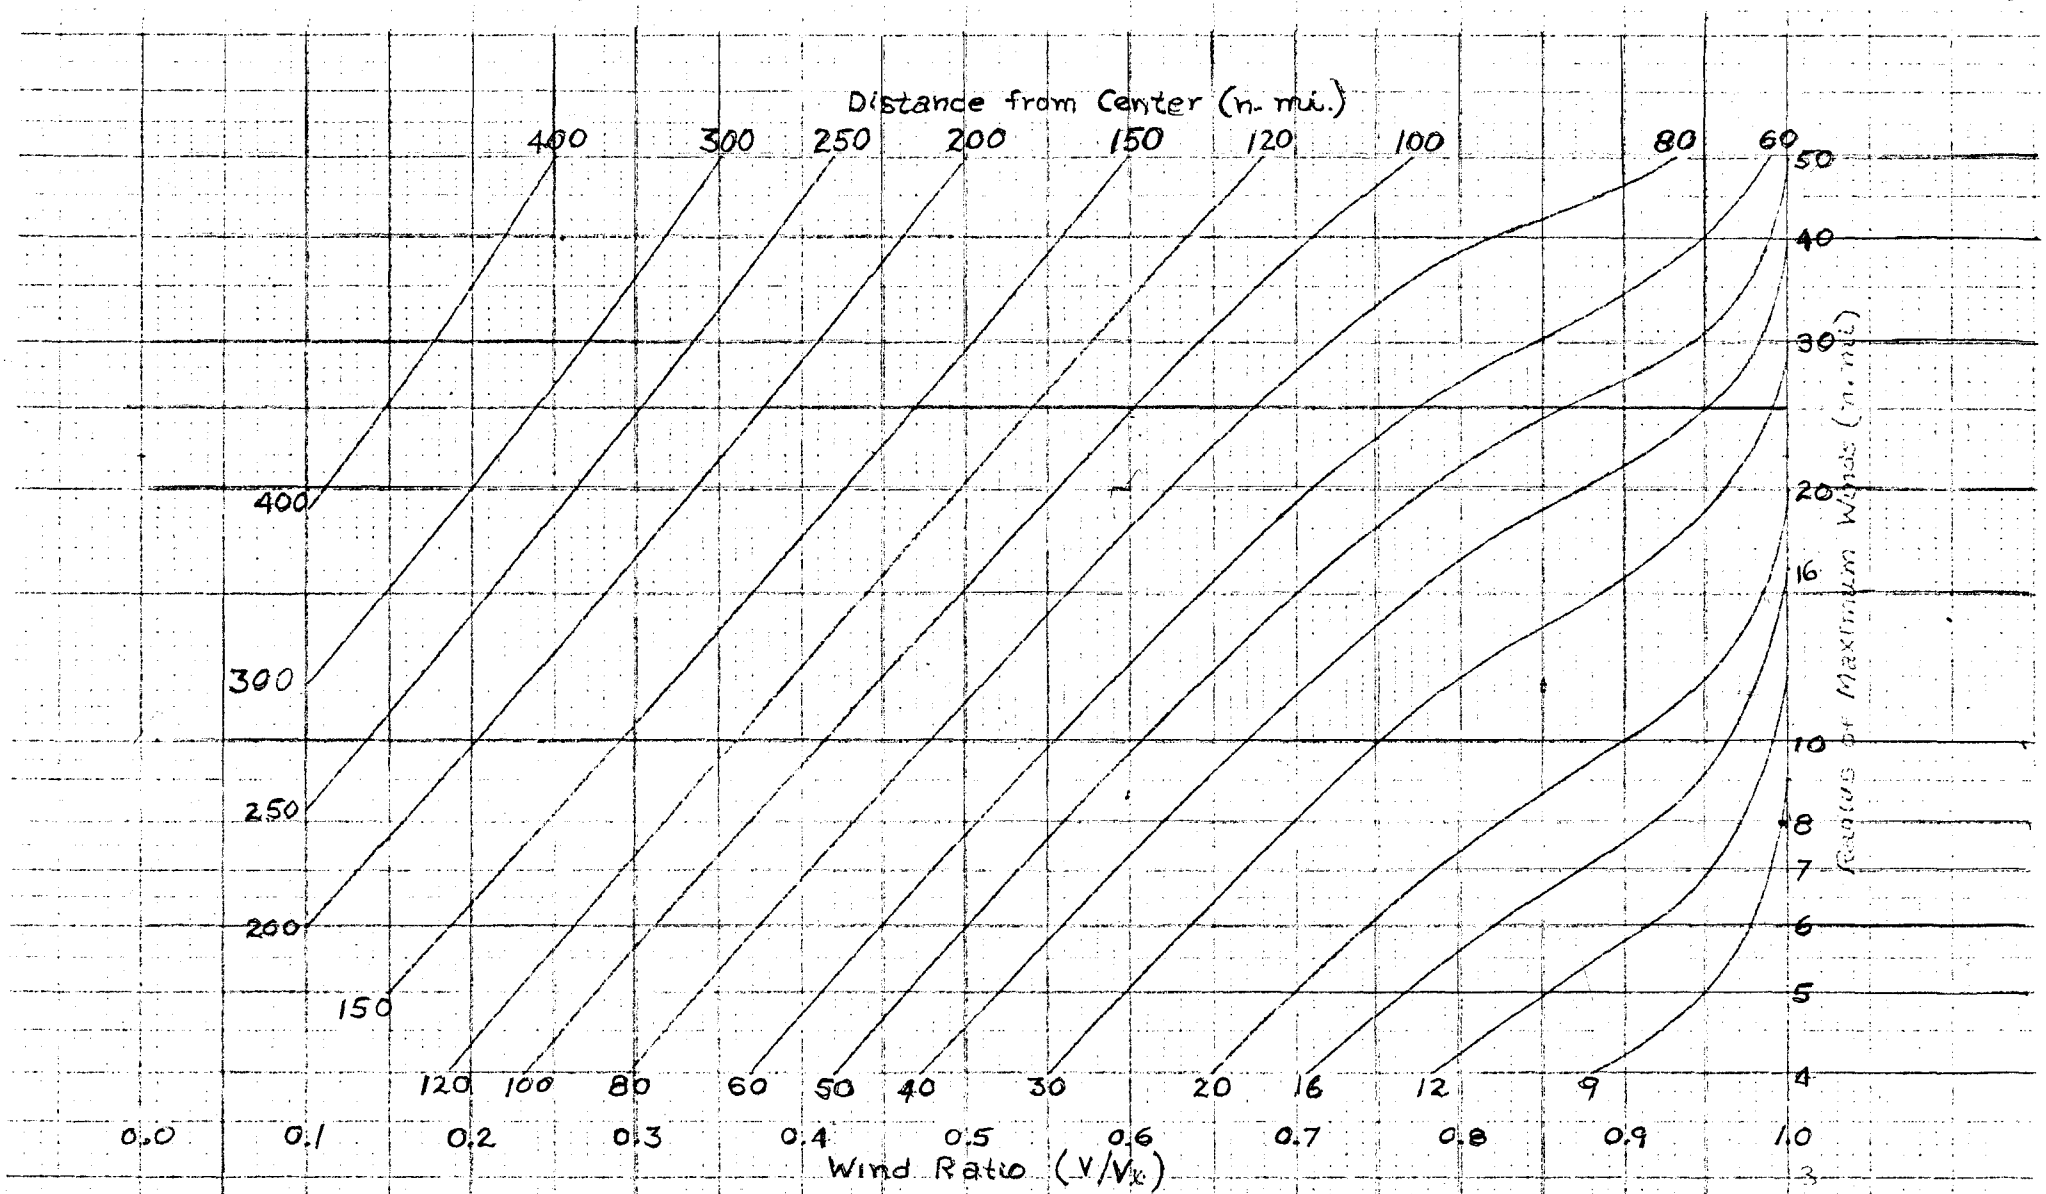

Fig. 12

NOMOGRAM FOR DETERMINING WIND PROFILE

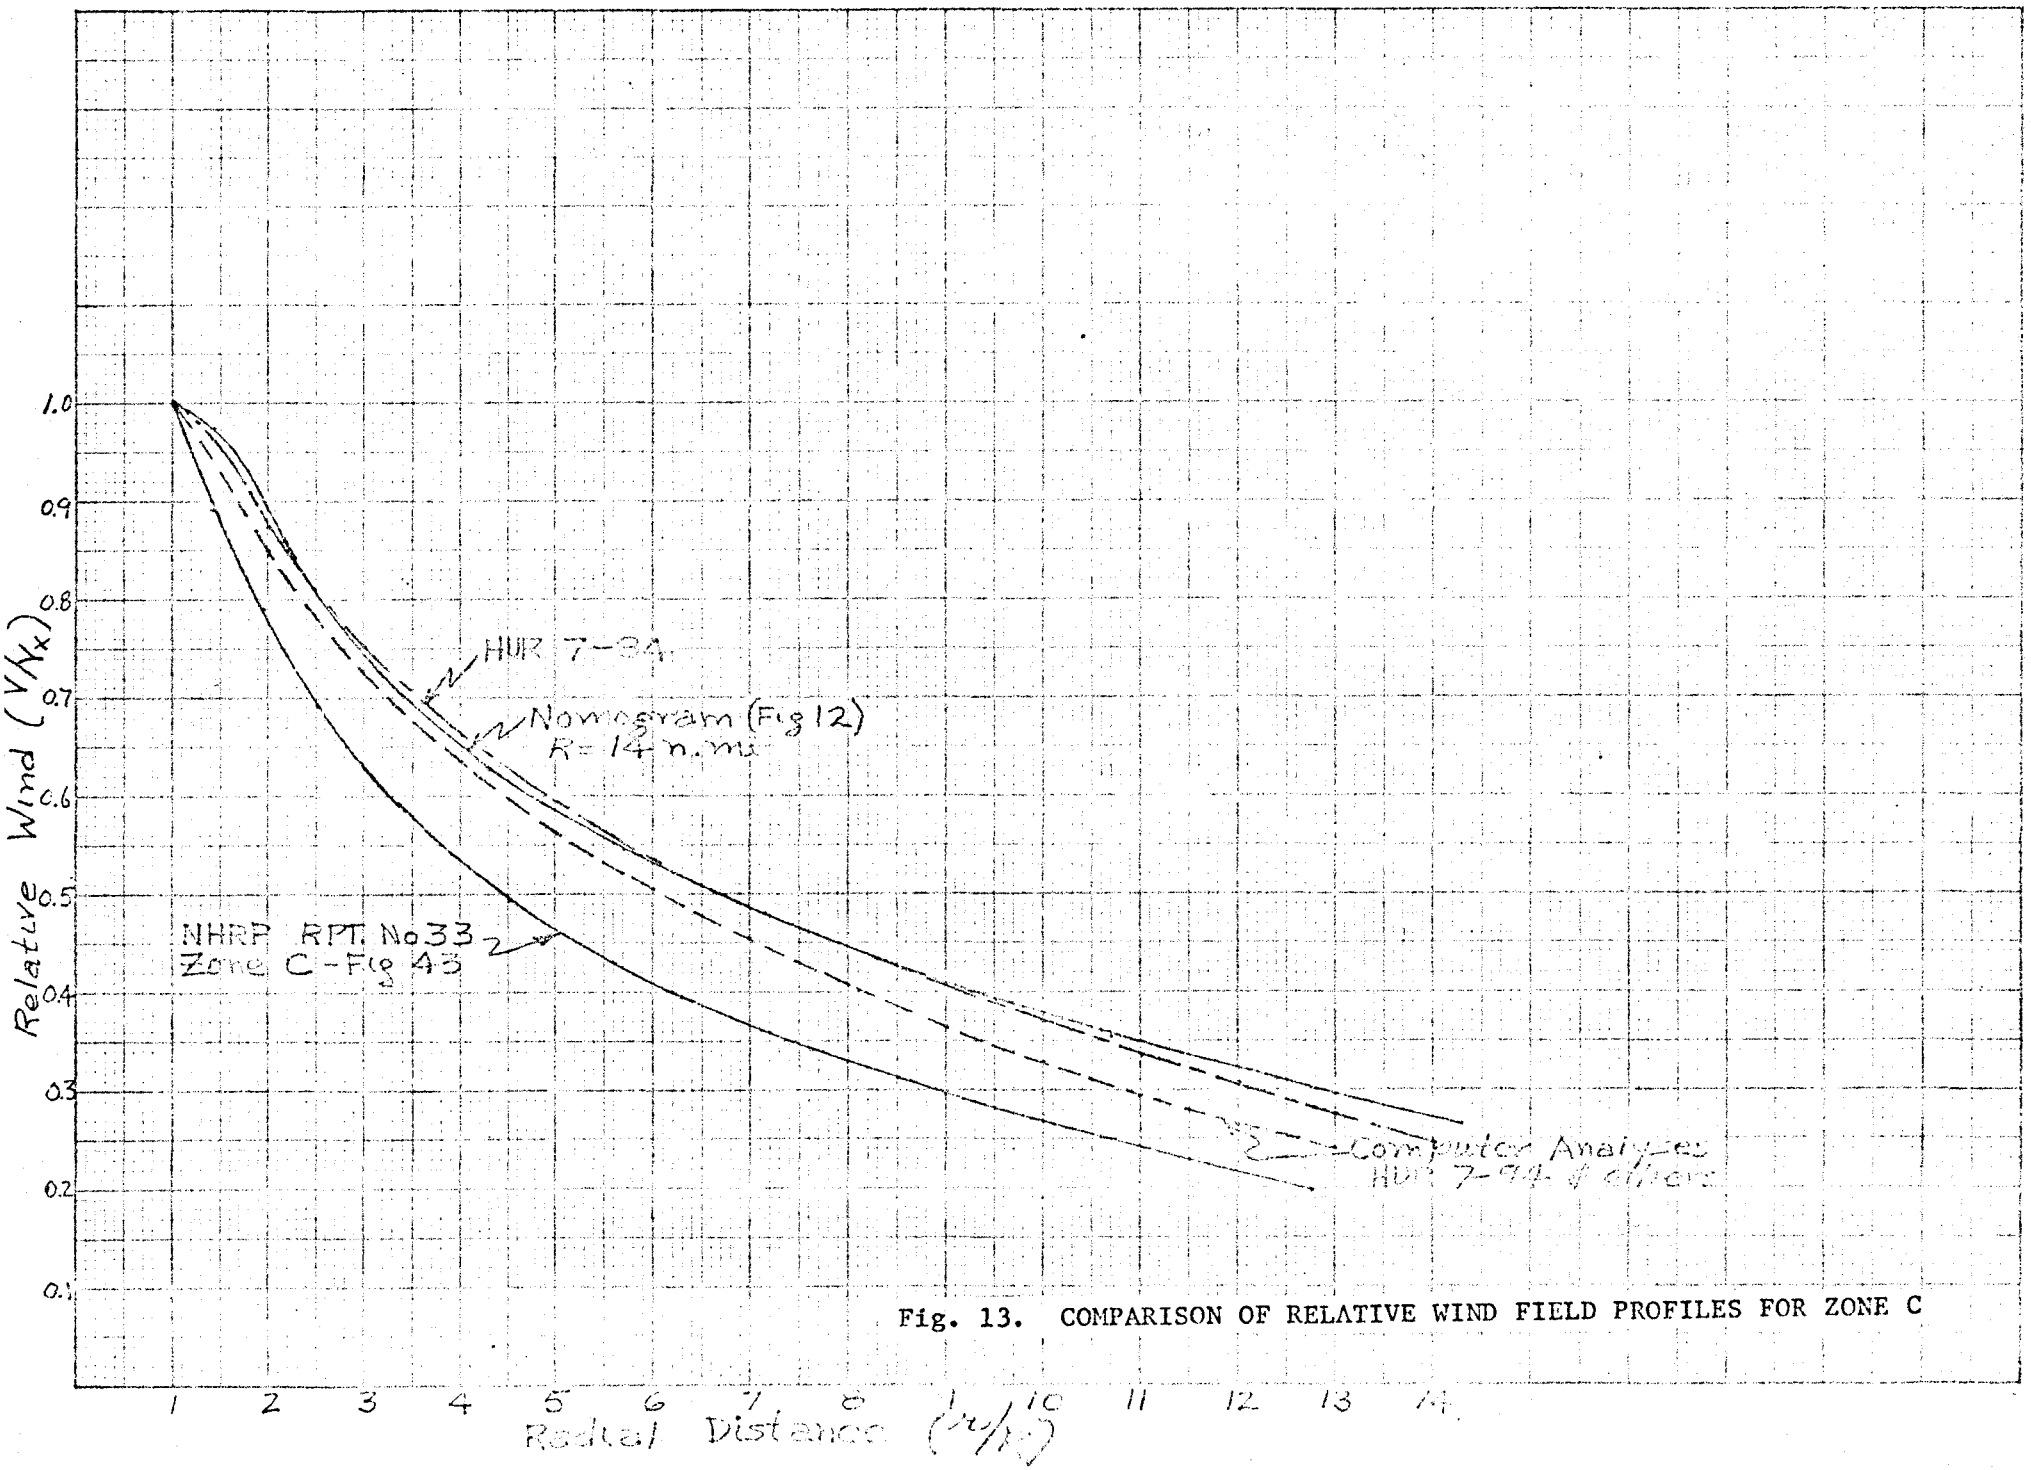

Fig. 13. COMPARISON OF RELATIVE WIND FIELD PROFILES FOR ZONE C

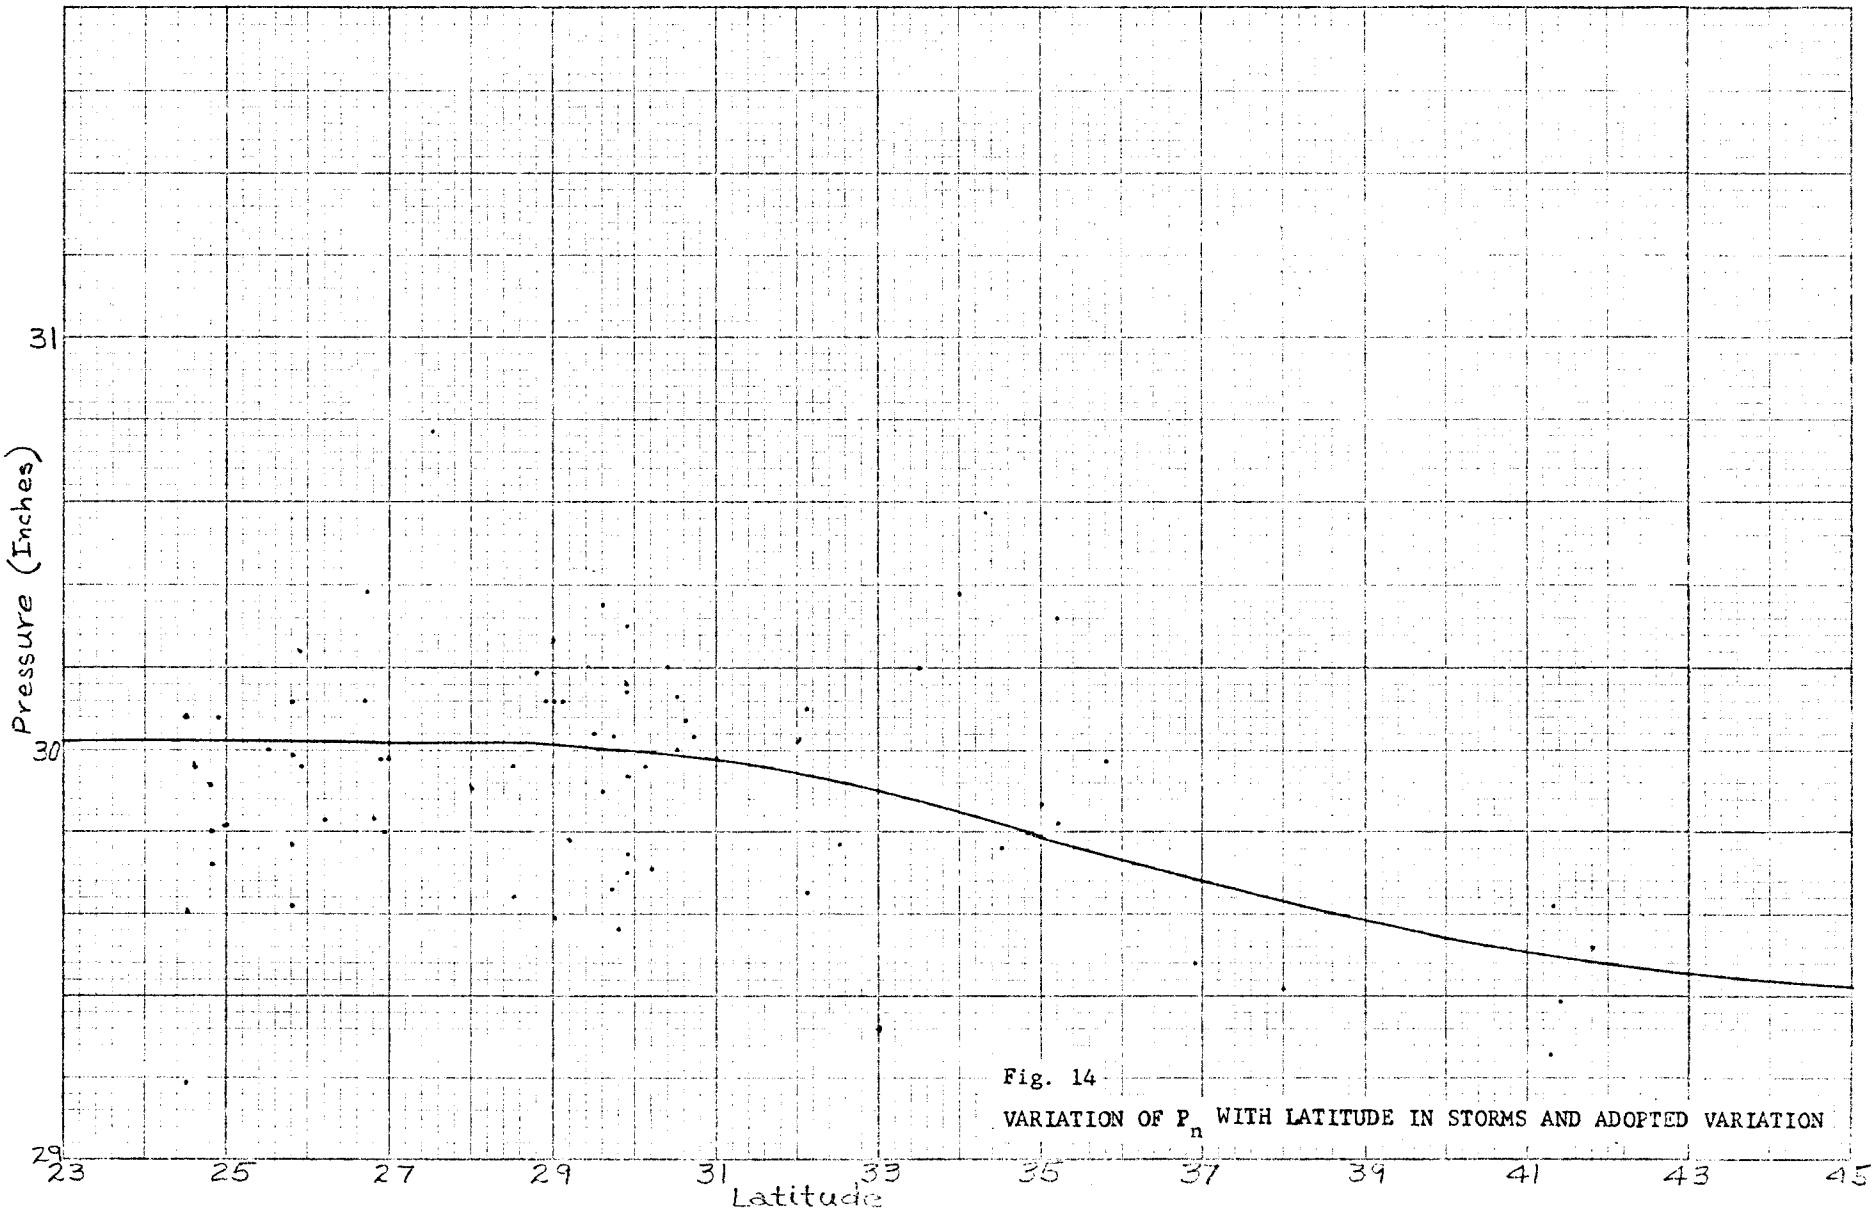

Fig. 14

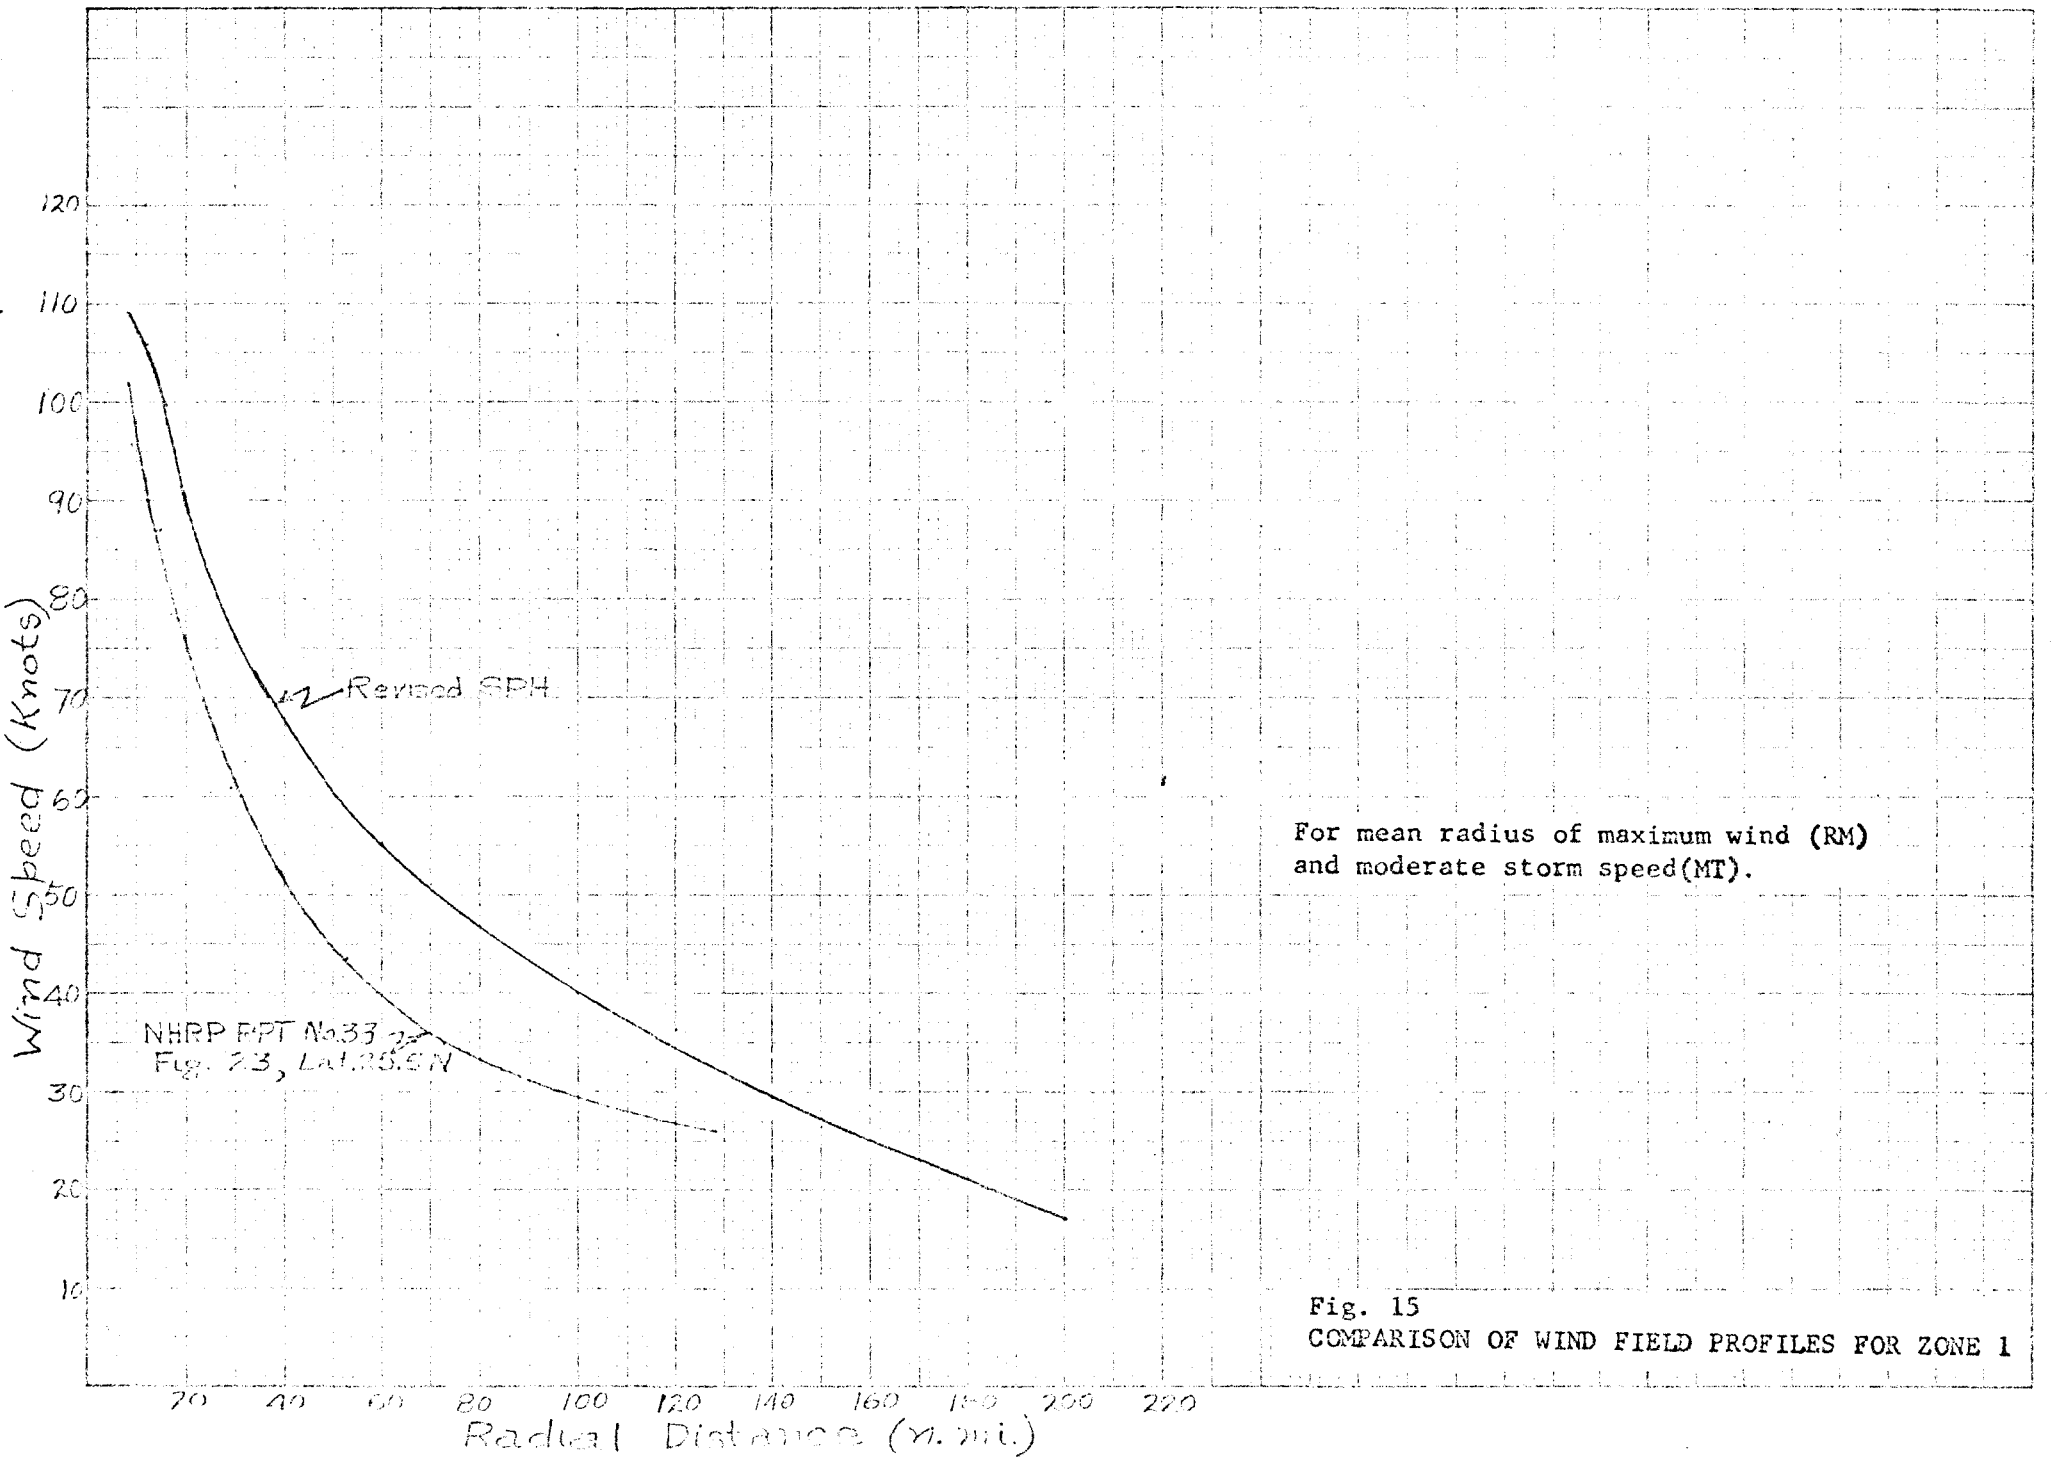
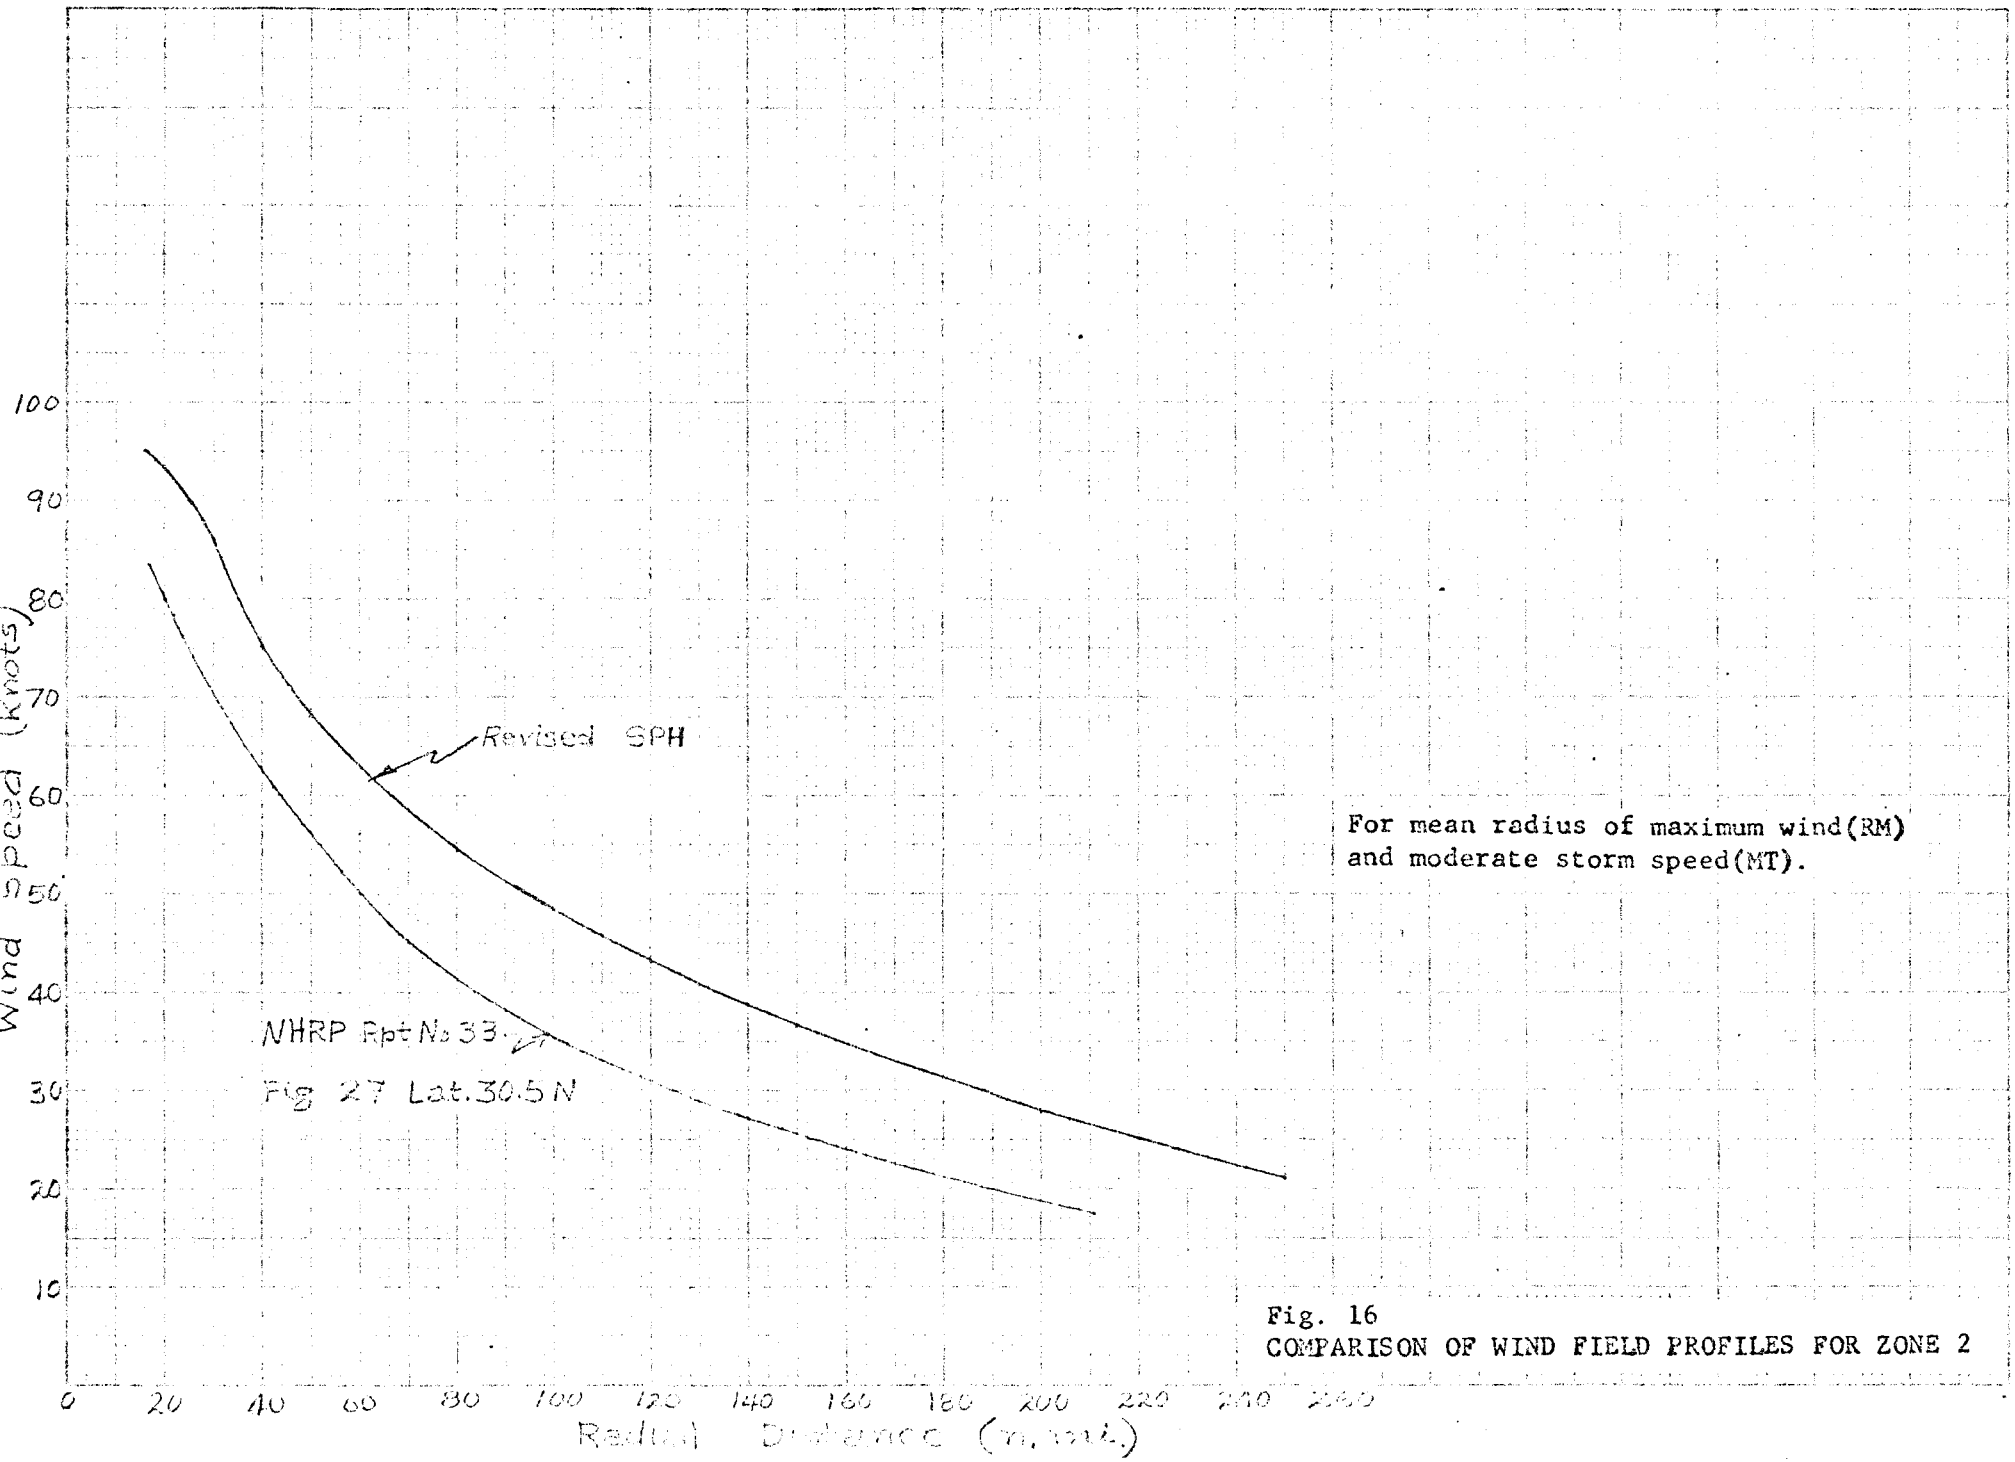
VARIATION OF P_n WITH LATITUDE IN STORMS AND ADOPTED VARIATION



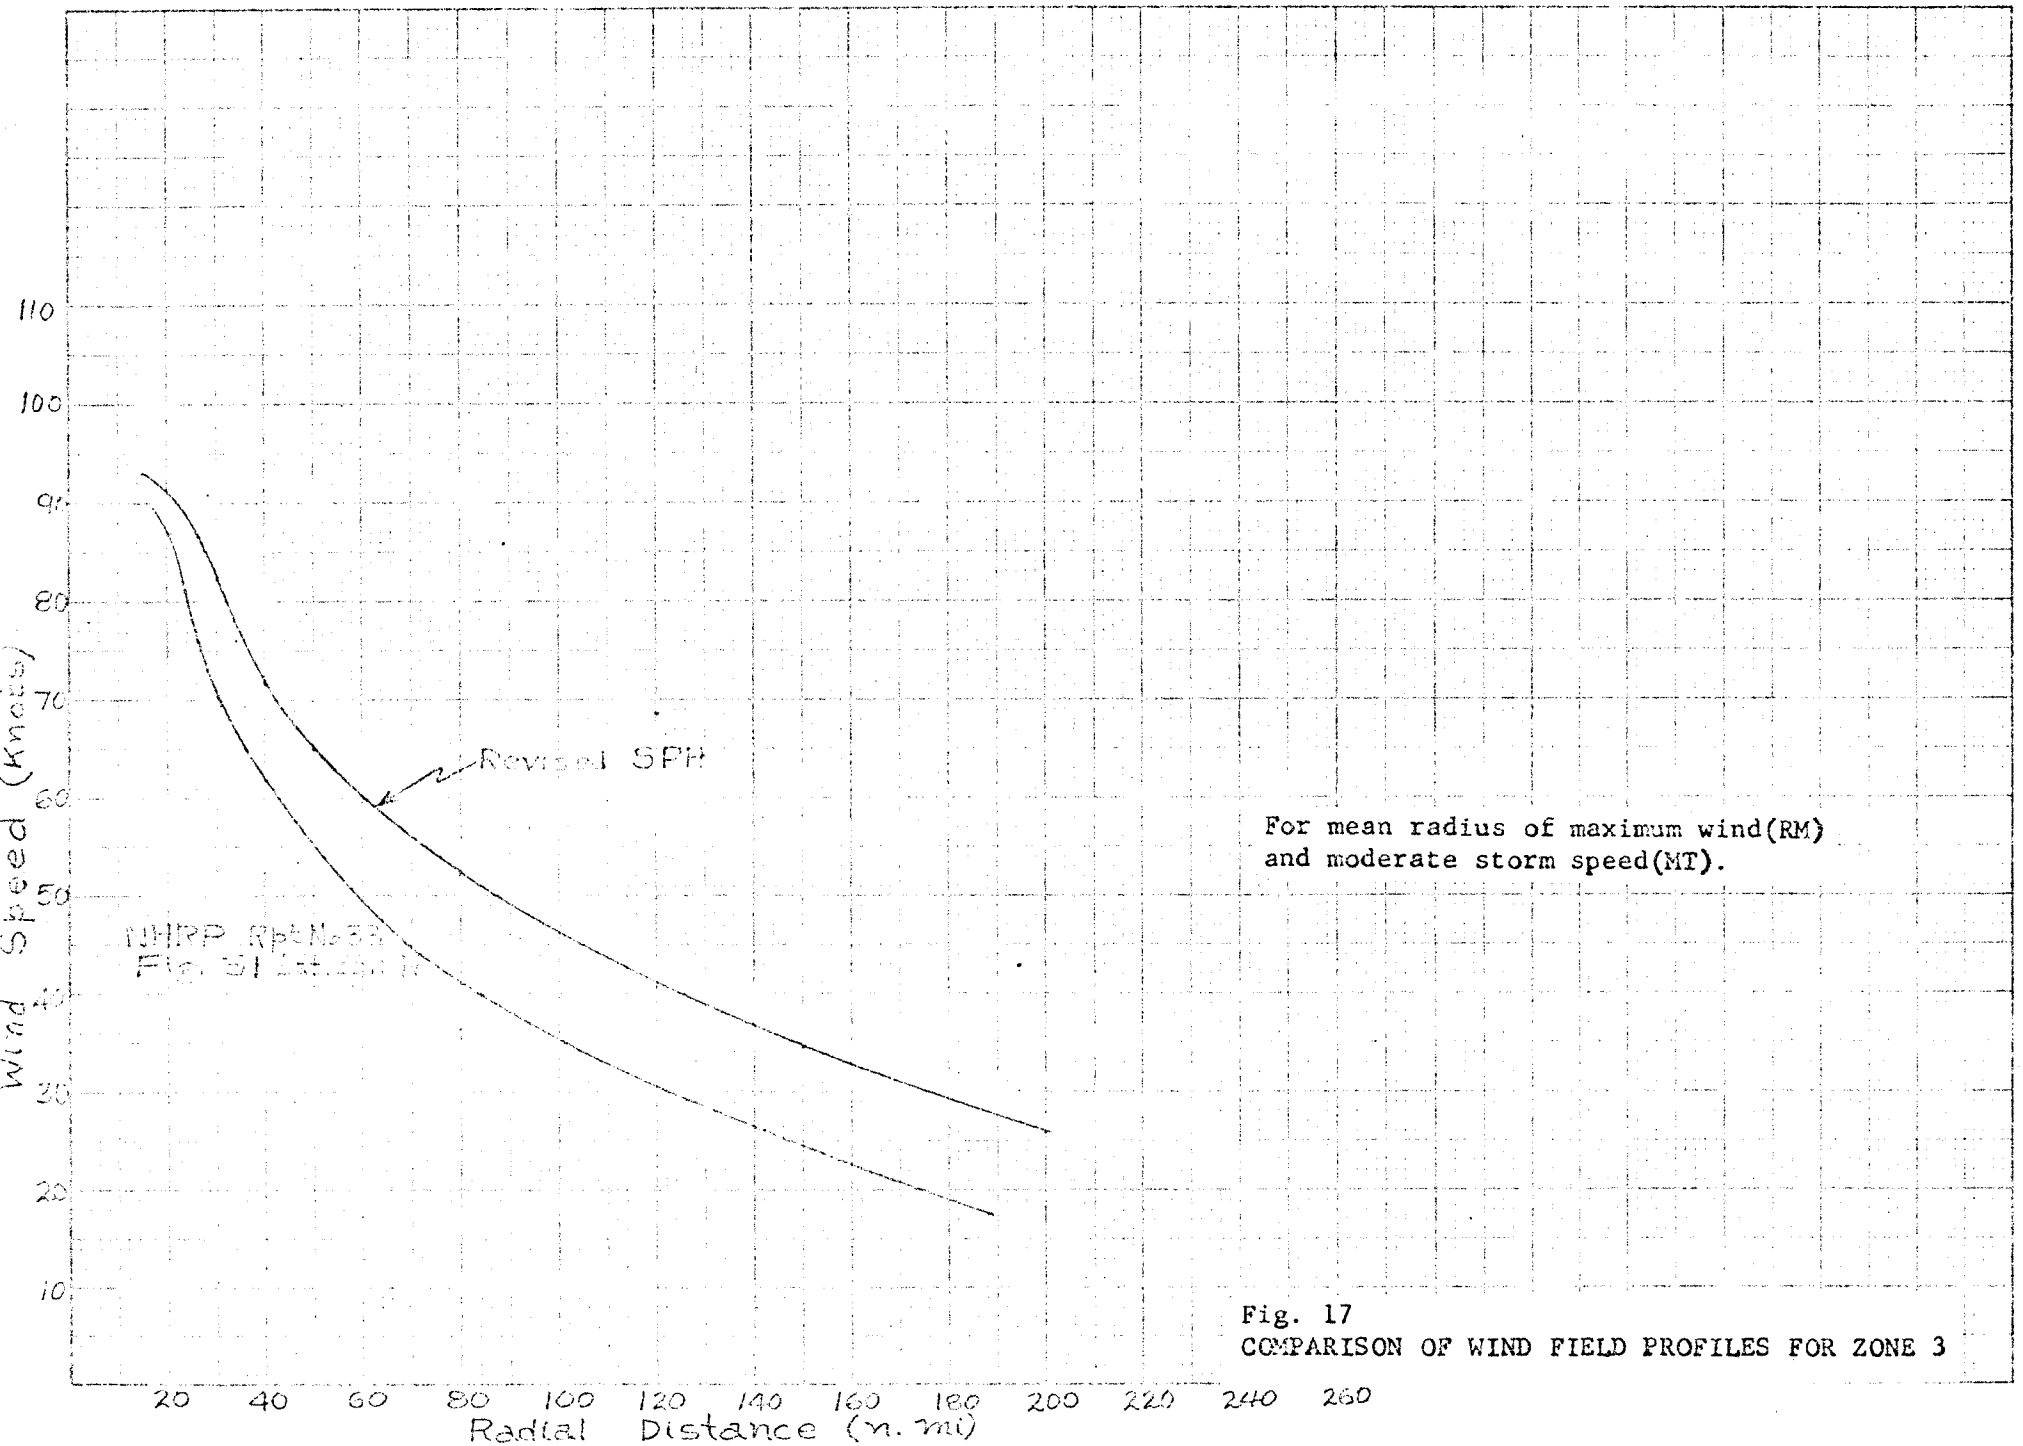
For mean radius of maximum wind (RM) and moderate storm speed(MT).

Fig. 15
COMPARISON OF WIND FIELD PROFILES FOR ZONE 1



For mean radius of maximum wind (RM) and moderate storm speed (MT).

Fig. 16
COMPARISON OF WIND FIELD PROFILES FOR ZONE 2



For mean radius of maximum wind(RM) and moderate storm speed(MT).

Fig. 17
COMPARISON OF WIND FIELD PROFILES FOR ZONE 3

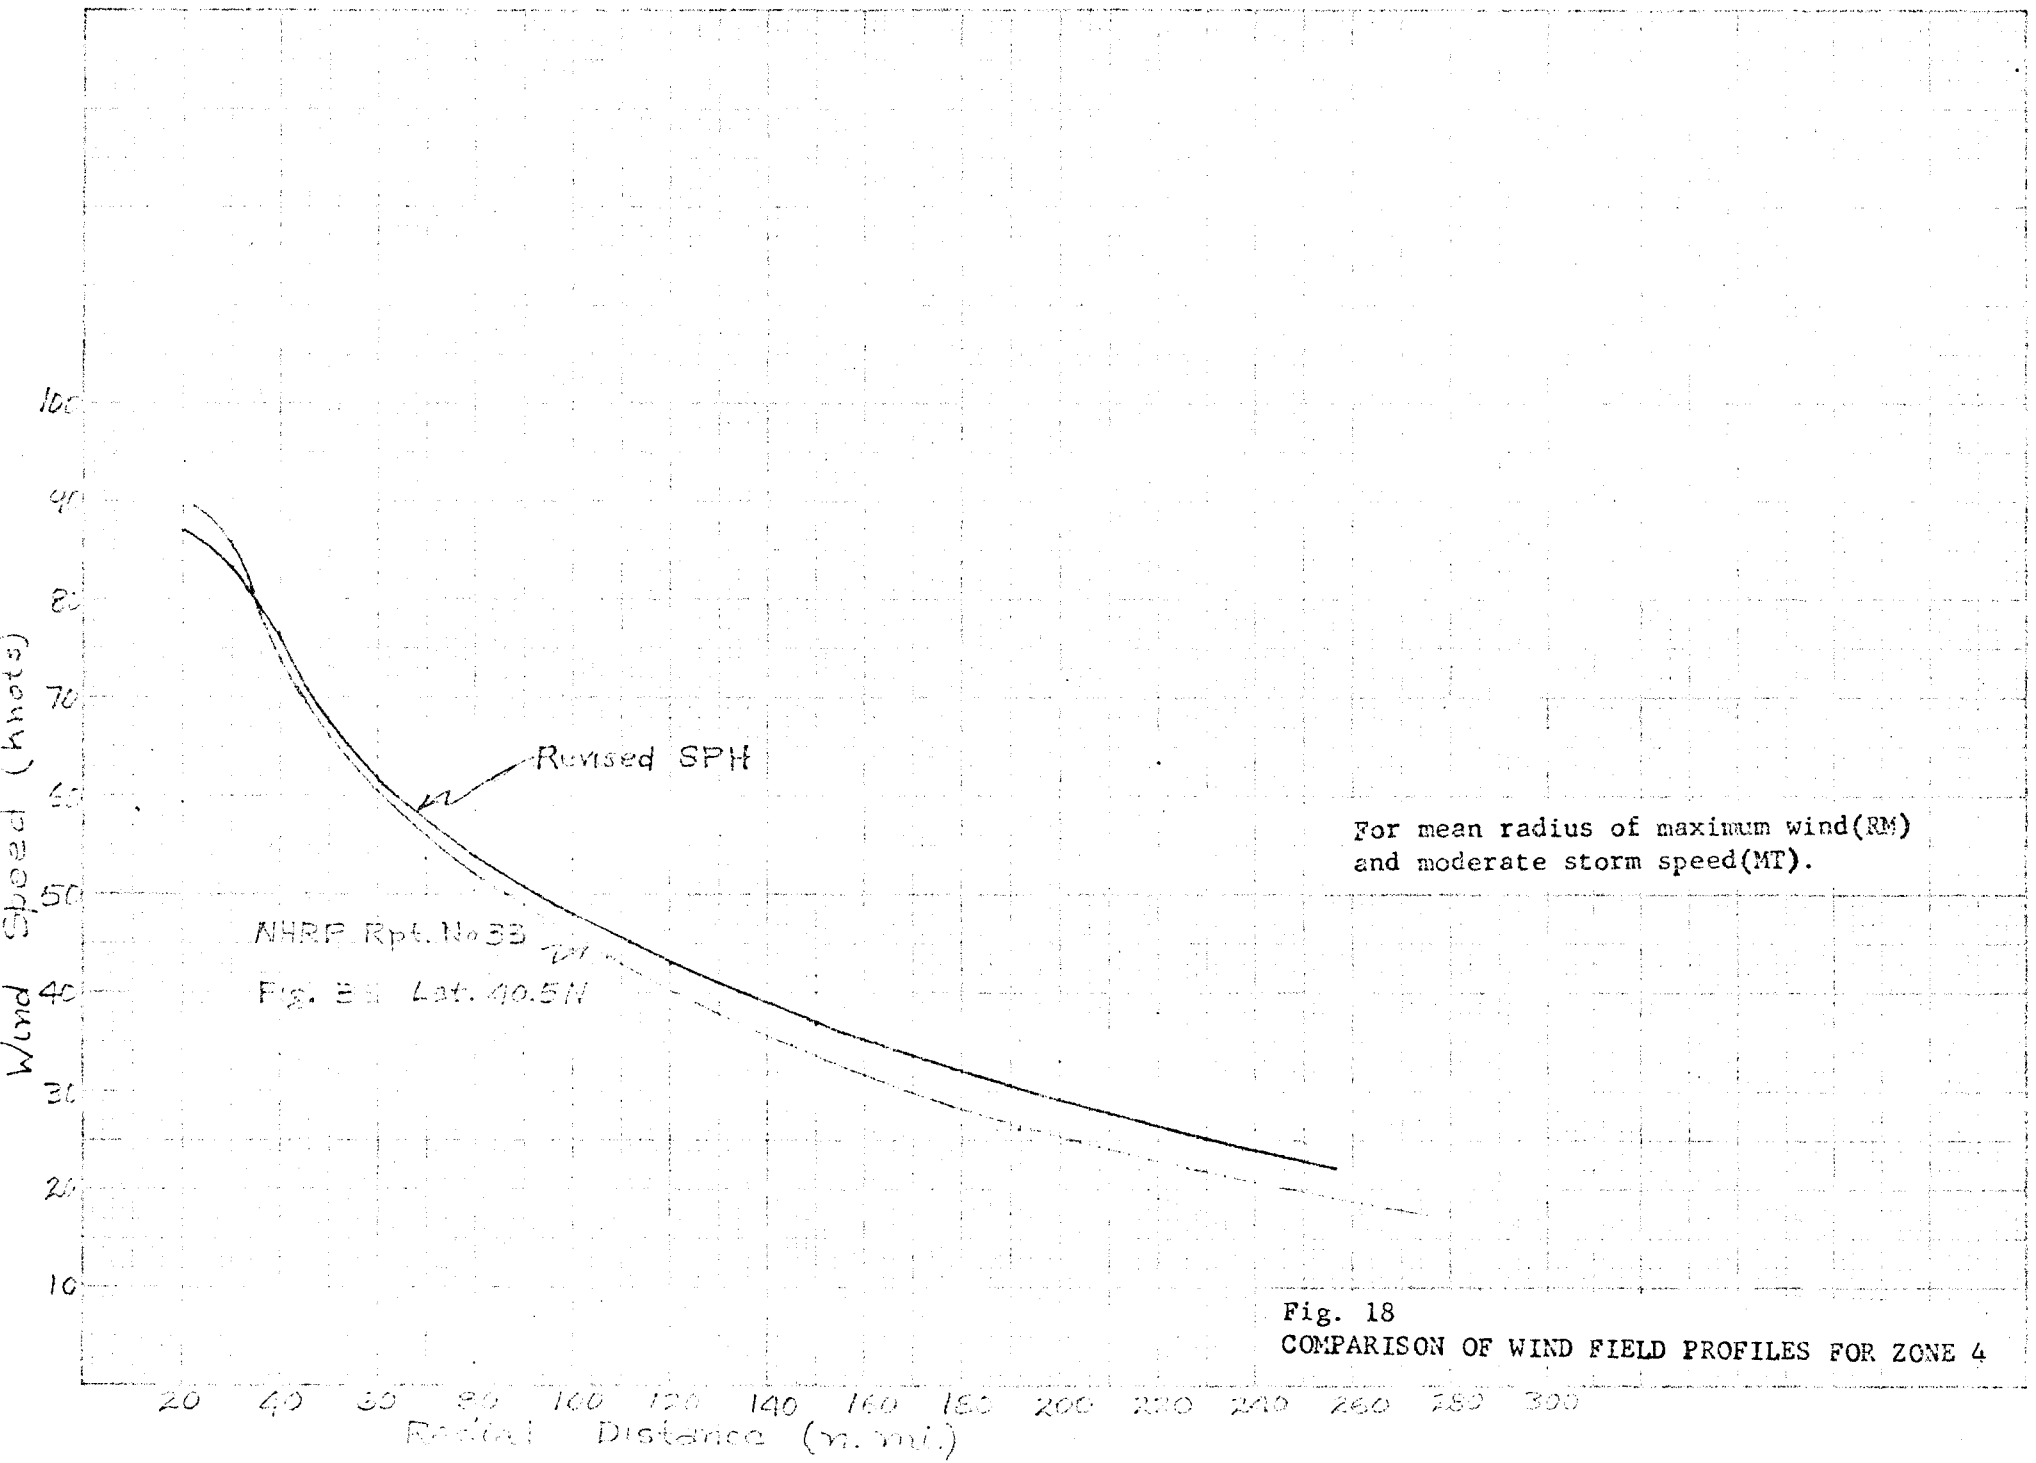


Fig. 18
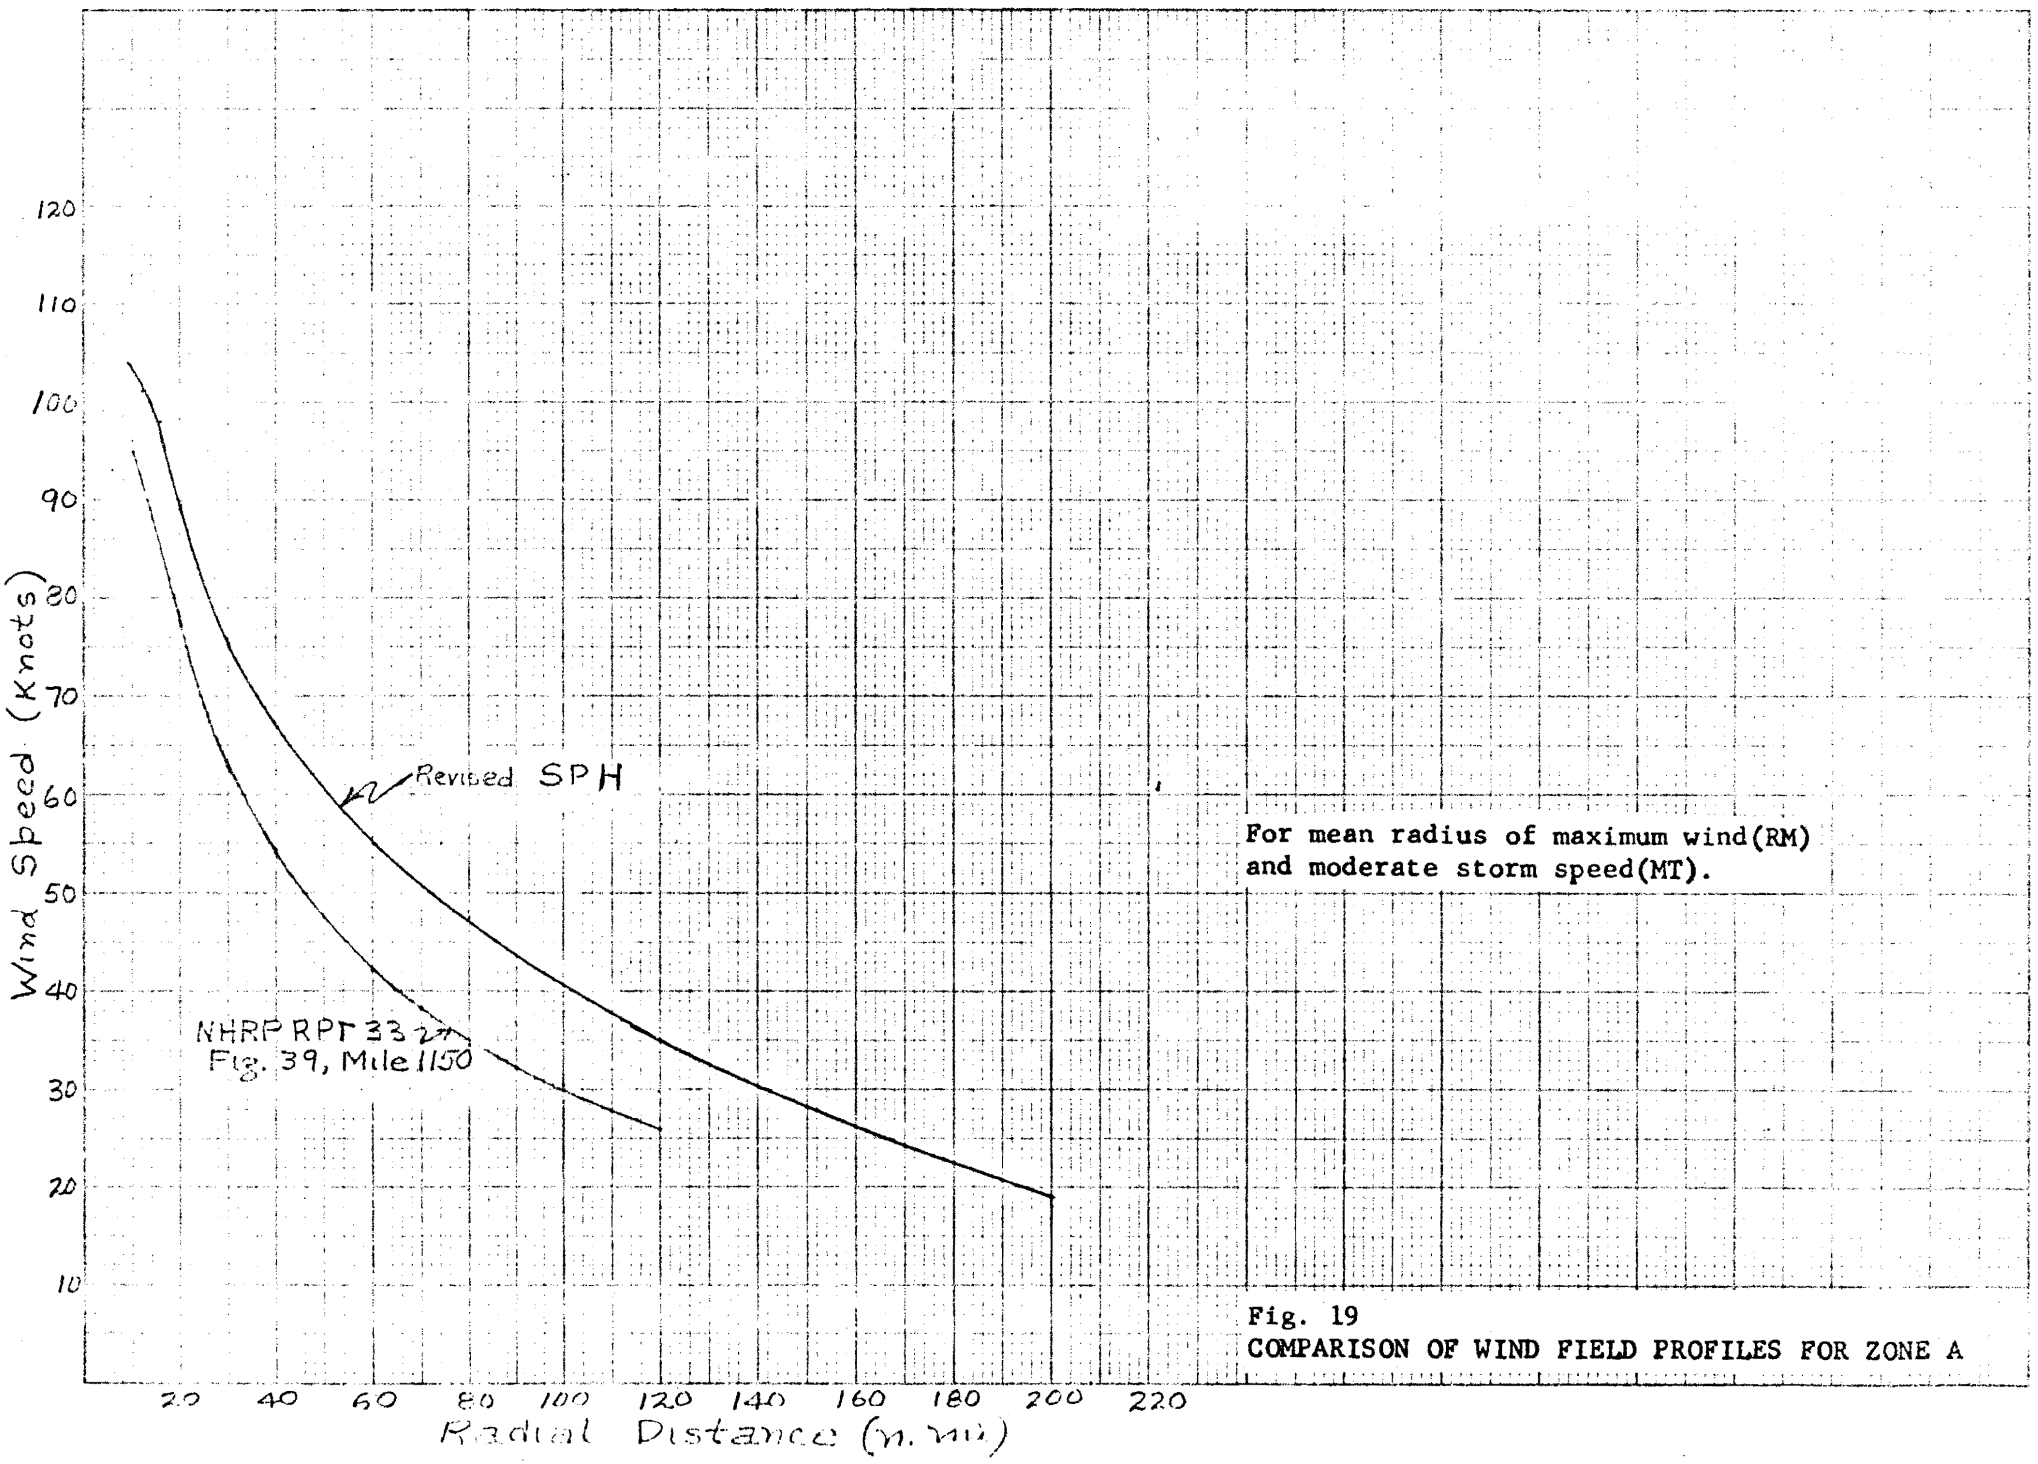
COMPARISON OF WIND FIELD PROFILES FOR ZONE 4



For mean radius of maximum wind (RM) and moderate storm speed (MT).

Fig. 19
COMPARISON OF WIND FIELD PROFILES FOR ZONE A

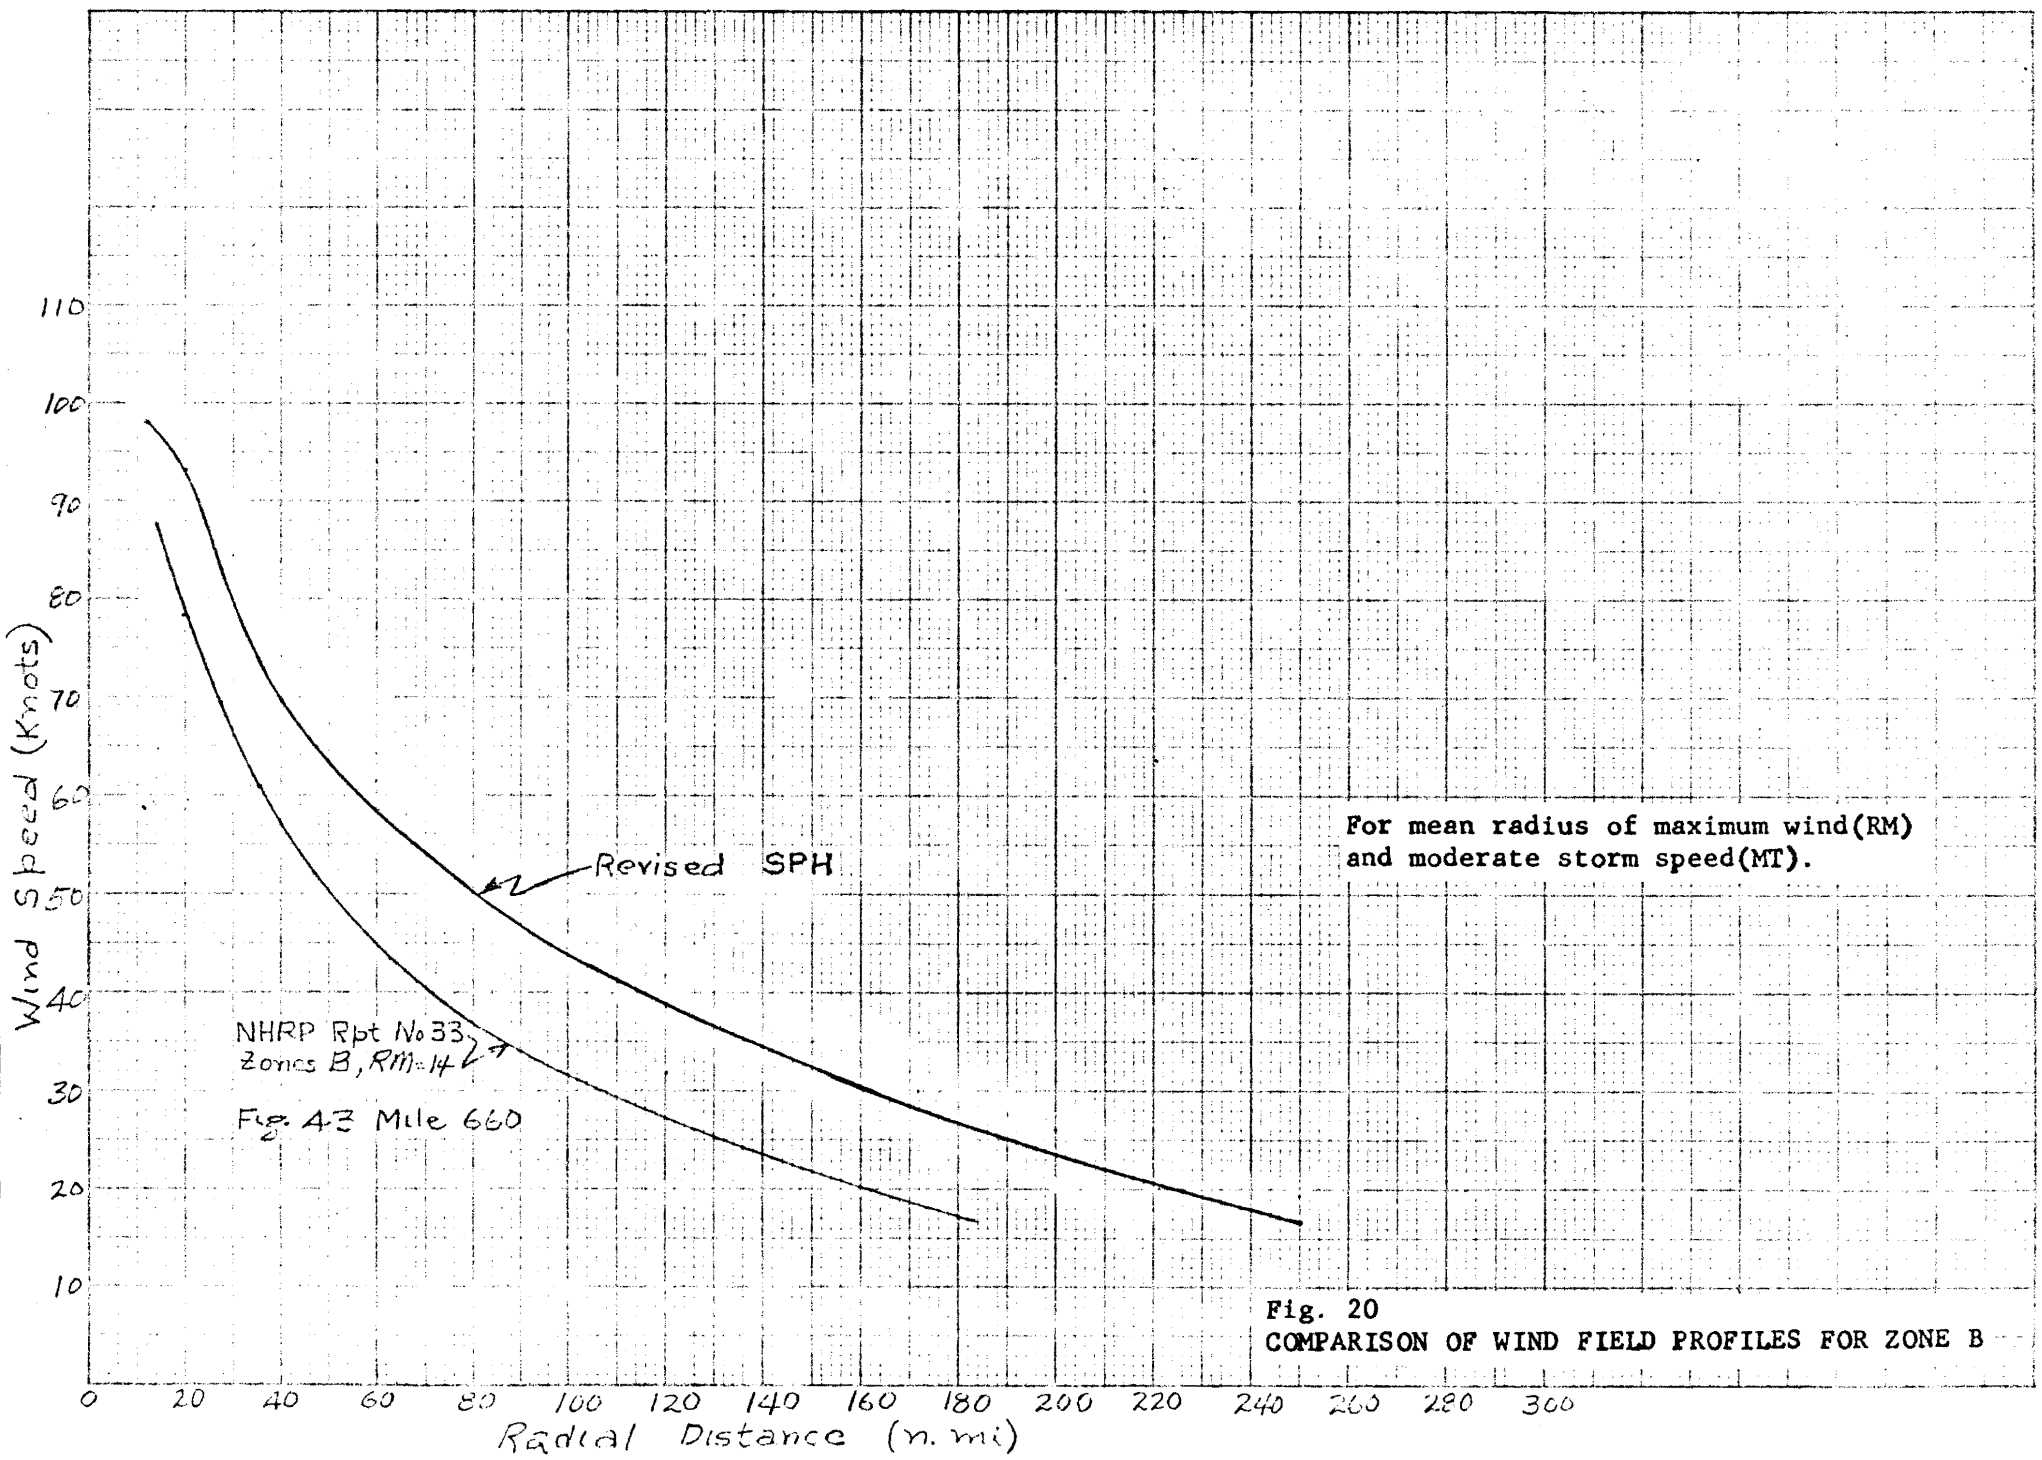


Fig. 20
COMPARISON OF WIND FIELD PROFILES FOR ZONE B

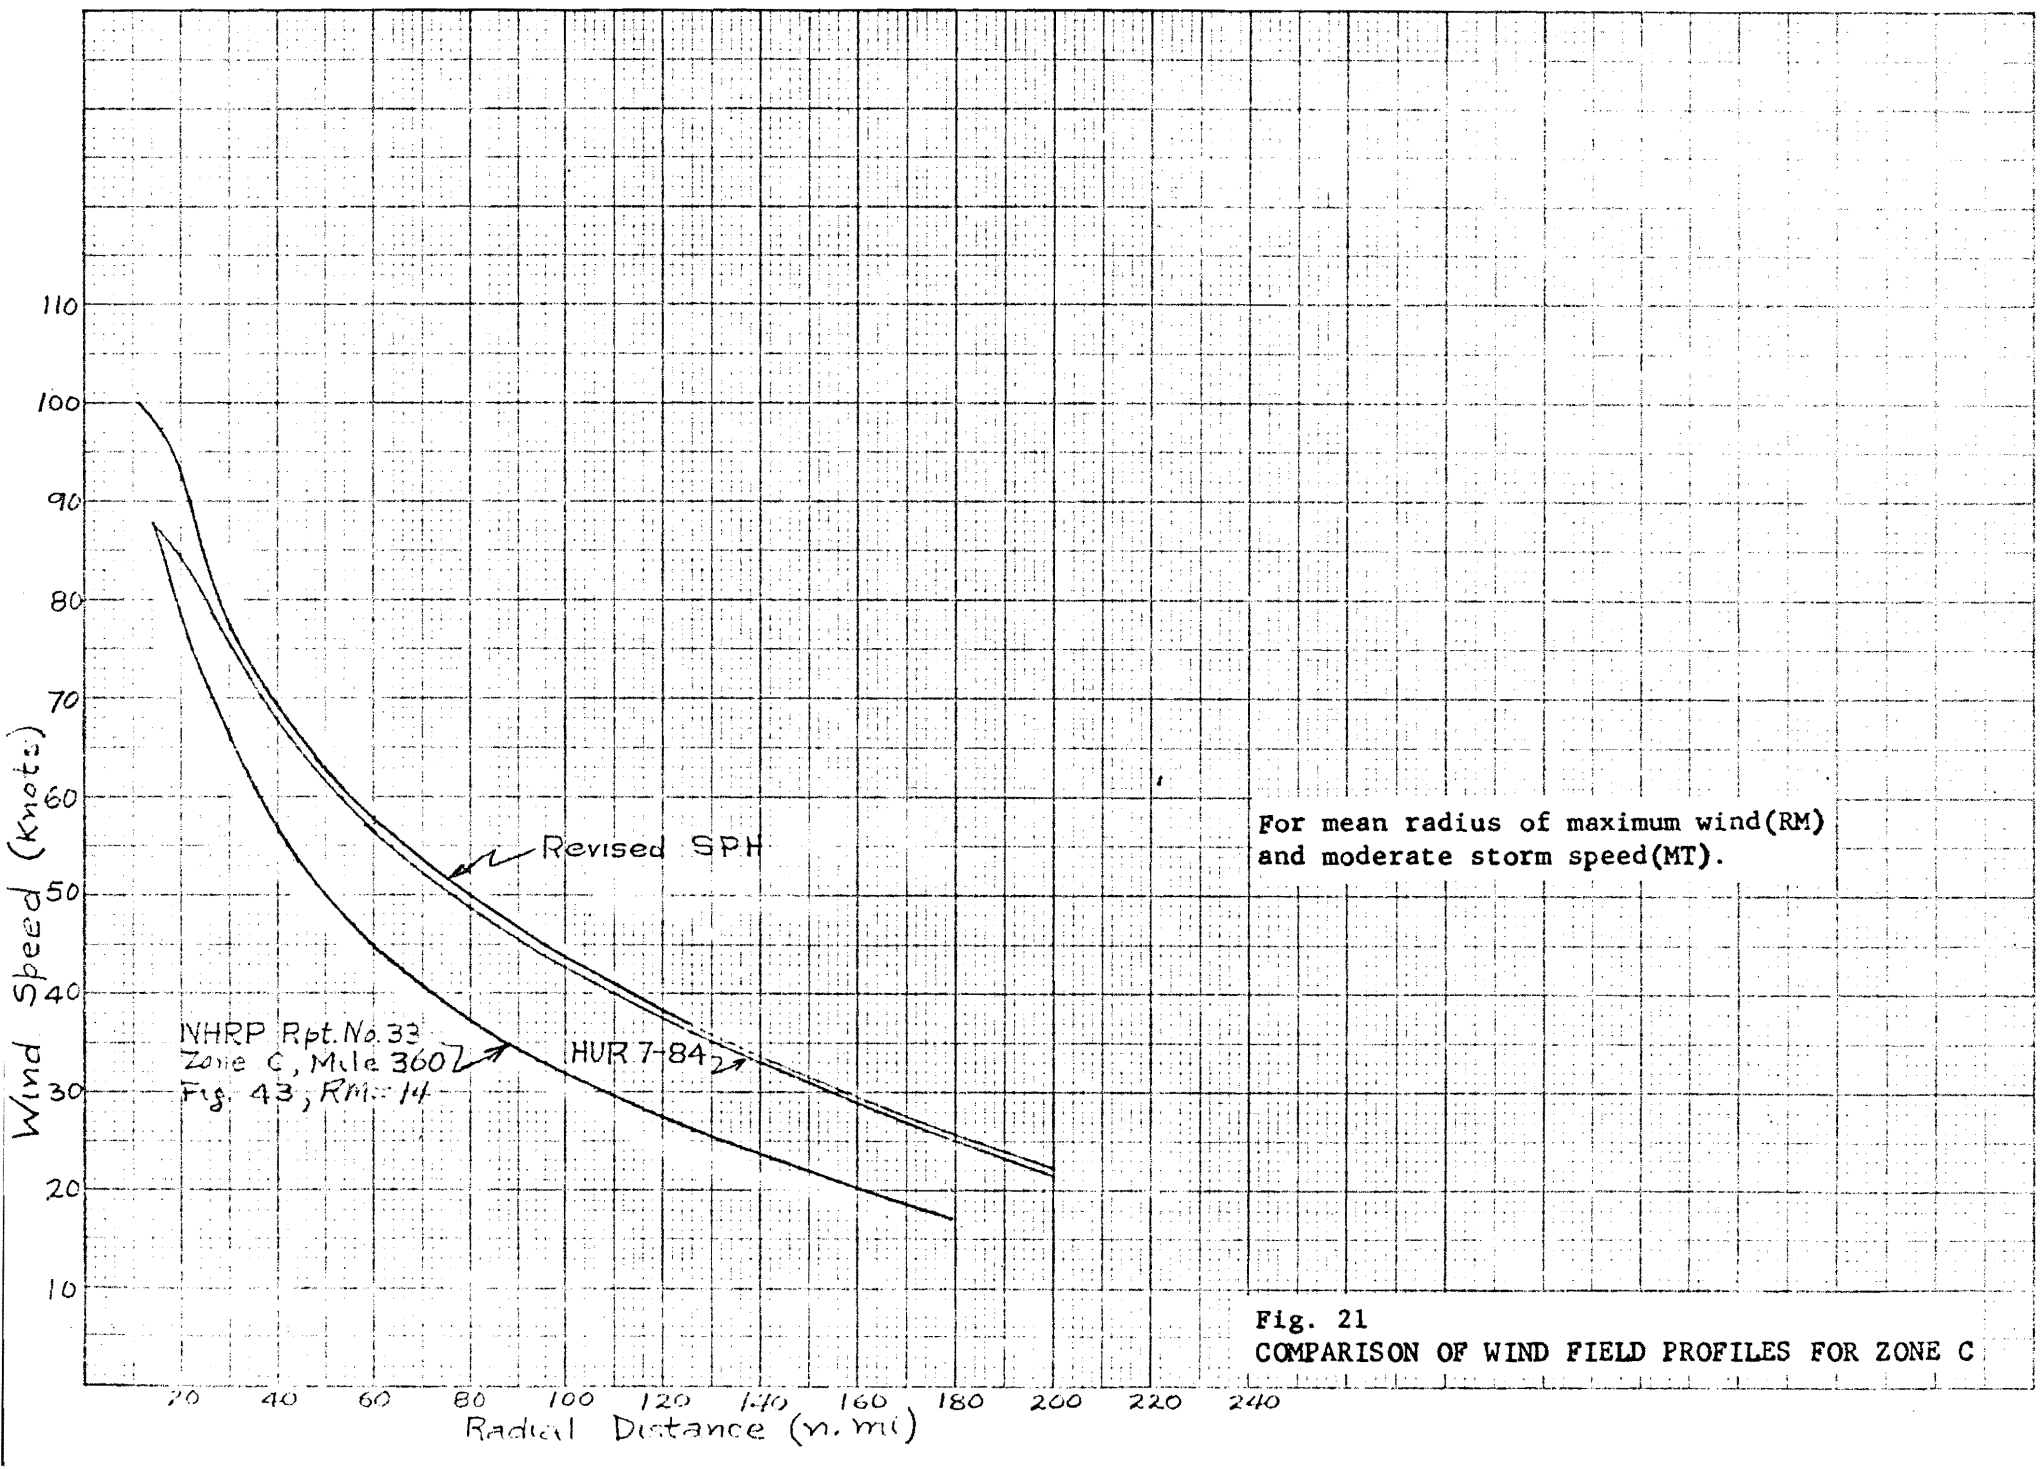

Fig. 21
COMPARISON OF WIND FIELD PROFILES FOR ZONE C

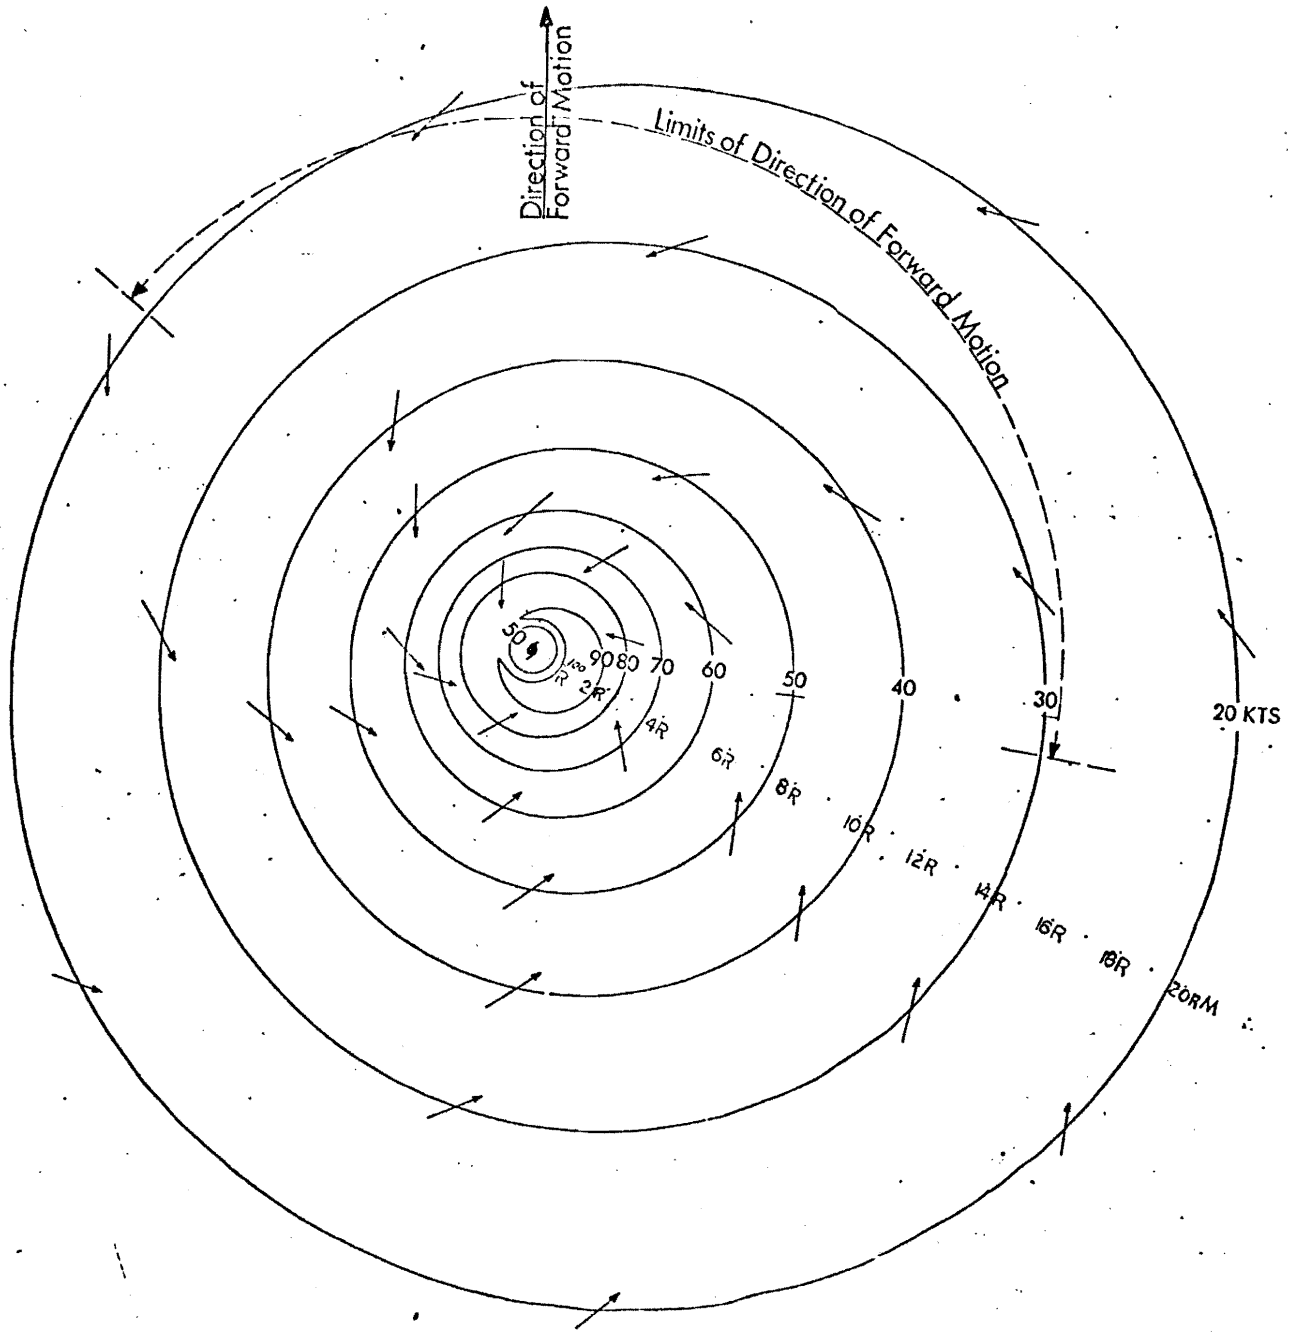

Fig. 22

EXAMPLE OF REVISED SPH WIND FIELD, ZONE C

Mean radius of maximum wind and moderate storm speed.

6-16-72

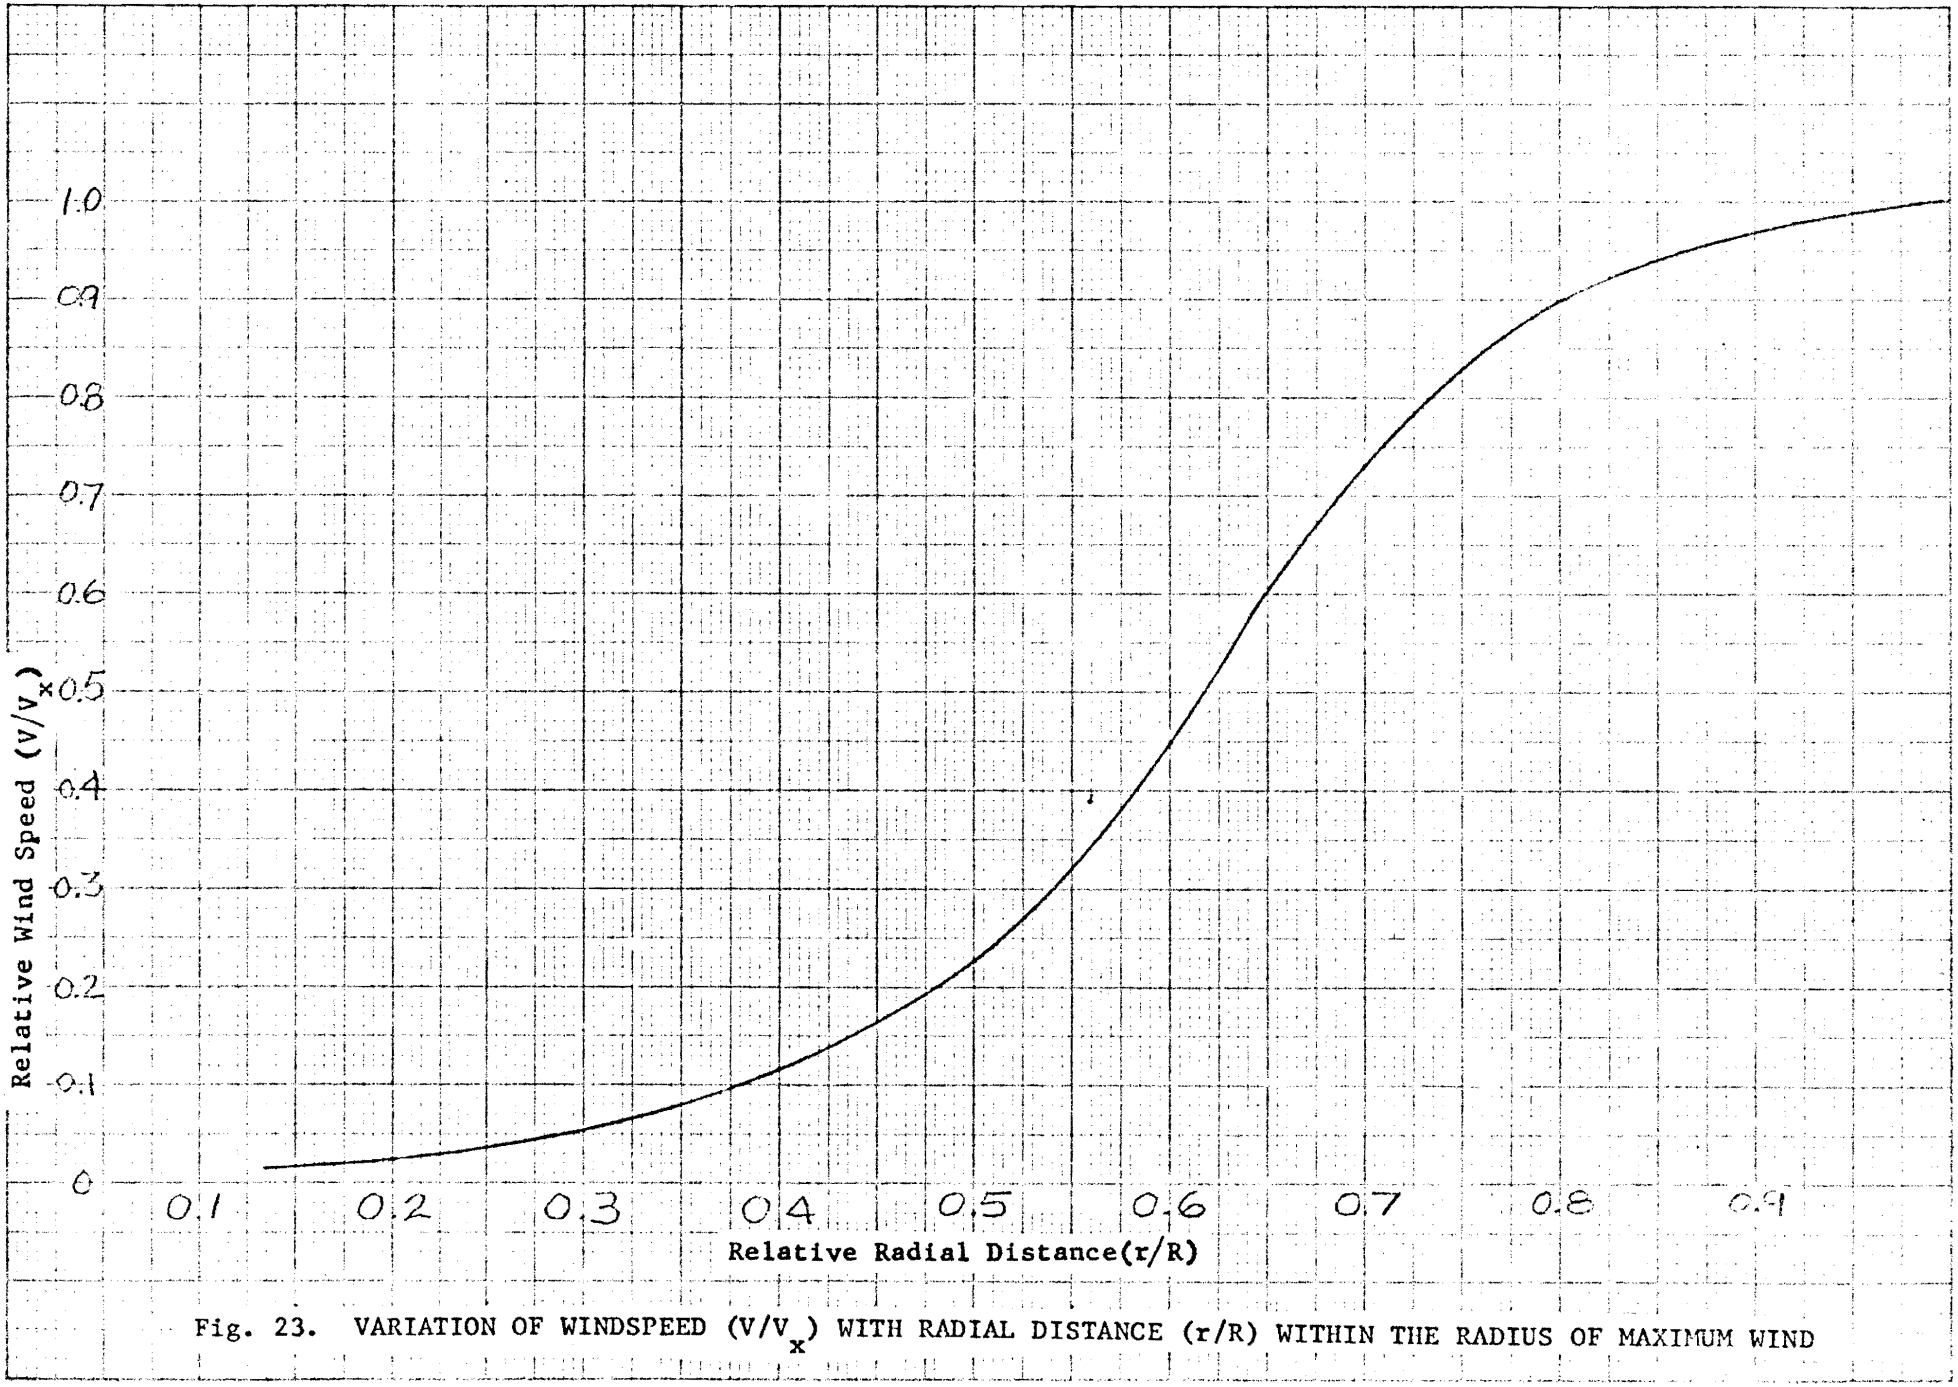

Fig. 23. VARIATION OF WINDSPEED (V/V_x) WITH RADIAL DISTANCE (r/R) WITHIN THE RADIUS OF MAXIMUM WIND

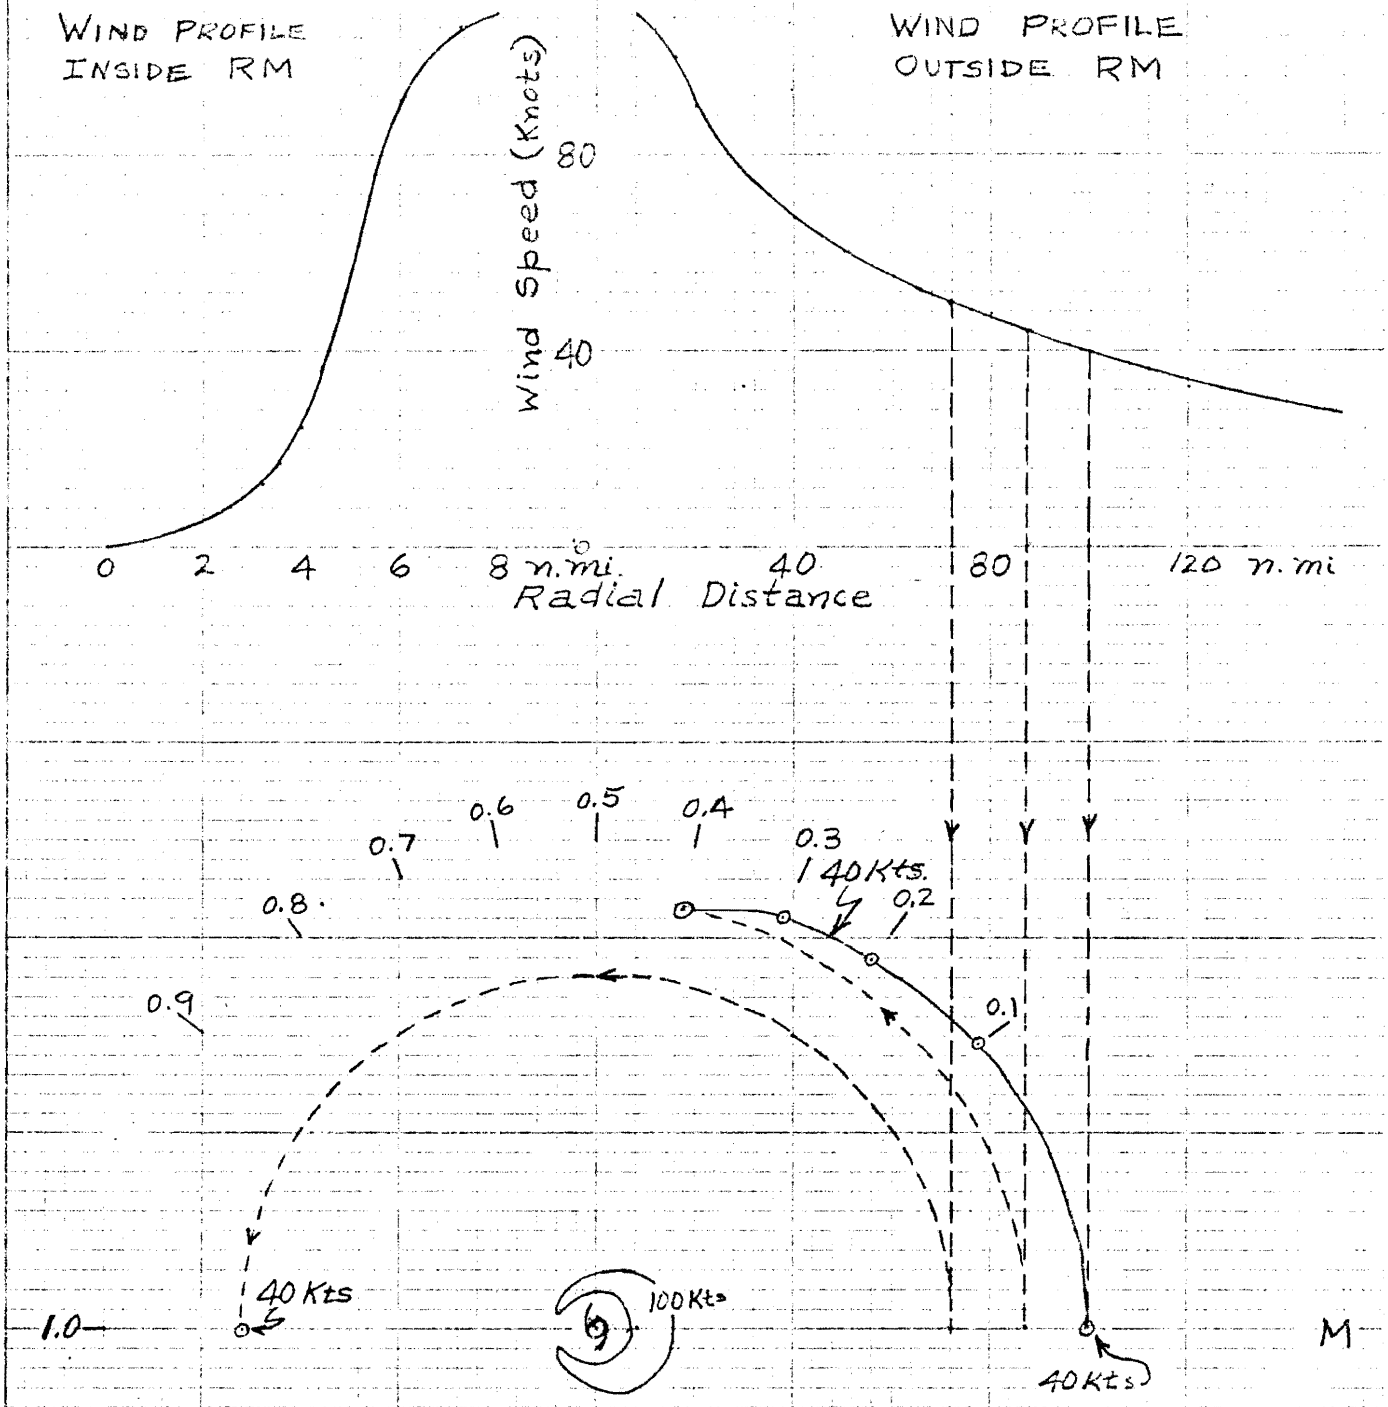

Fig 24
EXAMPLE OF WIND FIELD CONSTRUCTION

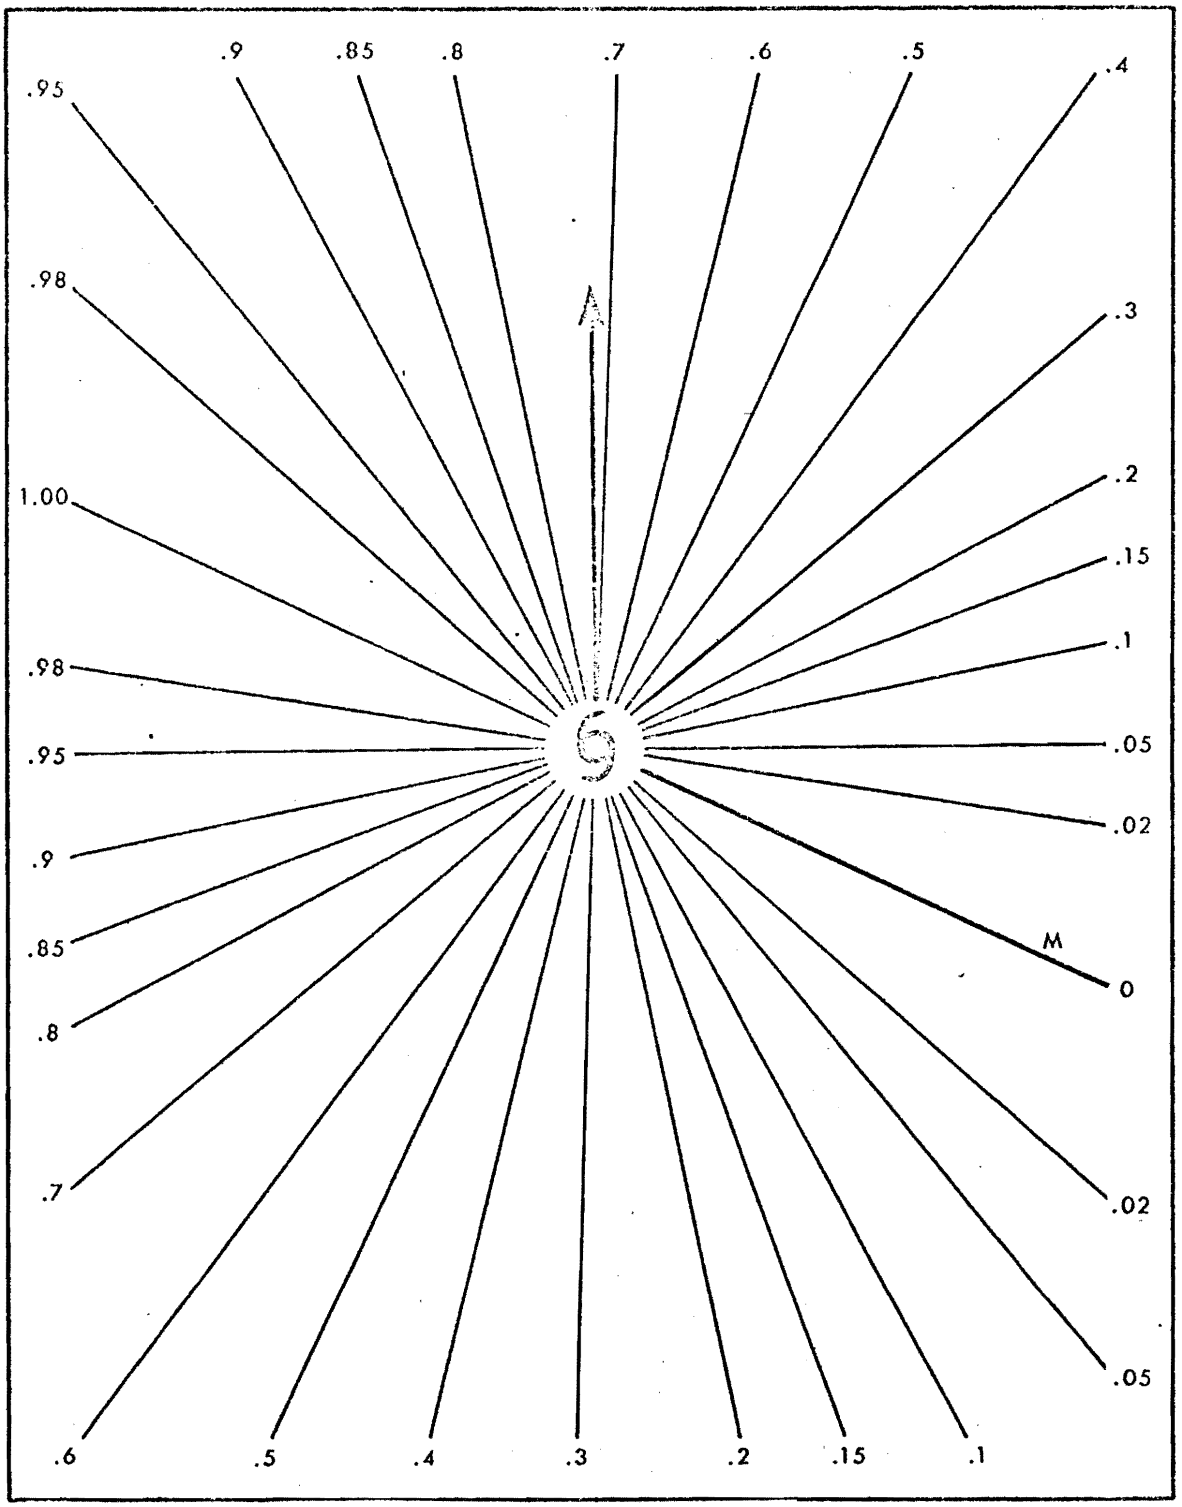

Fig. 25
NOMOGRAM FOR WIND FIELD ASSYMETRY FACTOR

Values are ratio of storm speed(T) to be subtracted from maximum wind profile.
